LECTURE IX.

—
Urethritis and its Metastases—Vaginitis.

SUCH is the most usual progress of urethritis; but do not imagine that such is its necessarily invariable progress, as I, who have seen it in various latitudes, and different modes of life, can testify. In the crowd of armies, in hot climates, I have seen this inflammation followed by serious consequences in men who seemed to brave it, and committed all manner of excesses during the time they were suffering under it. On such occasions I have seen it occupy the penis and prepuce with its utmost fury, produce phymosis and gangrene, occasion the loss of the penis, and even penetrate the interior of the body. At other times, when the patients used a stimulating regimen, and forced the secretory action of the testicles by the abuse of venery, the inflammation passing along the ejaculatory canal, became communicated to the testicles, and occasionally even extended to the vesiculæ seminales, causing their suppuration. This last case is rare; but it is more common, after urethral inflammations thus exasperated, to see the vesiculæ obliterated and sterility ensue. As, however, these inflammatory extensions begin the history of cystitis—the vesiculæ being adherent to the bladder—I shall not proceed further with them at present, but confine myself to the testicle, in which, when the inflammation has reached it, there is first of all injection of the epididymis, and then inflammatory gorging of the gland itself, or orchitis. The phlegmasia proceeds with varied rapidity, according to the violence of the inflammation in the urethra, as also according to the mode of life and treatment. It is a revulsion from that of the urethra,

which it suspends. Mark well this phenomenon: you will find its analogy in many other circumstances, where you may see the prior inflammation leave surfaces far more extensive than is the urethra, while a more acute inflammation is developed elsewhere. Testicular inflammation may be communicated to the scrotum itself, and cause suppuration of it and of the testicles, or even gangrene, especially in hot climates, and in individuals predisposed to inflammation. It is a mere pretence to assign a fixed march and termination to the affection in question. Diseases proceed according to temperaments and latitudes, and so does this—a truth that medical men, who have never left their own clime, have great difficulty in comprehending, and which is explicable by the degrees of irritation. If you refuse to admit it, you are driven to make as many morbid entities as there are individual temperaments, and this again will lead you to nosologies more rich in names than the dictionary of the Academy: you may do this if you please, but you will soon find how ridiculous it is.

In common cases, such as are seen in these climates, orchitis is confined to a swelling of the testicles, with redness of the scrotum, pain of the epididymis, and shining of the skin. Hydrocele is often a consequence of it: indeed, the majority of affections of that kind are the effects of urethritis transferred to the testicles. When there is hydrocele you must not think that the tunica vaginalis of the testicles is always distended like a sac, so as to become transparent; after yielding to a certain extent, it may suppurate, contract adhesions, harden and thicken all around. The testicle surrounded by this thick and rugged sac is then exhibited as a sarcocele, without, however, any destruction of its organization; but at other times it degenerates of itself, after being excessively swelled, and violently distending the tissues. By carefully following the increasing and decreasing progress of these inflammations, these different terminations of them will be recognized.

But these are not all the unfortunate advances of urethritis. When not combatted,

and, *à fortiori*, when treated with ill-timed irritants, it may be propagated to the bladder, to the prostate, and the vesiculæ seminales, being then confounded with cystitis of the neck of the bladder, or go deep into the bladder, giving rise to cystitis of the body of the organ, or to vesical catarrh; and I may anticipate by stating, that the cystitis of the neck and of the body of the bladder have their peculiar characters, which will be hereafter mentioned. Lastly, urethritis may extend along the ureters as far as the kidneys, and occasion nephritis and gravel; this is not effected in a fortnight, but in the course of years, in subjects who have kept it in an exasperated or constantly renewing form for a long period. These disasters are more particularly observable in those following a military career, in those living in a state of celibacy, or leading an unsettled and agitated life; whereas, in a civil condition, when the comforts of home are in possession, and early opportunity of combating inflammation afforded, they are effectually prevented. These nephritic affections, with reference to their etiology, I was very slow in estimating, for they are scarcely at all mentioned in books. It was by the physiological method of viewing disease, the method that obliges me to follow irritation wheresoever it goes, that I obtained certain ideas on the subject; moreover, my station in the midst of great armies, furnished the opportunity of accumulating observations that I could not have procured elsewhere.

The above is not all; urethritis, shortly after its appearance, sometimes suddenly ceases, and is replaced by a visceral phlegmasia, or an articular inflammation. In this case, the knees are mostly swelled and dropsical; of this I have seen several instances, and I particularly remember a professional friend, who, after being kept to his bed a whole year from a similar cause, came to me (I was then abroad), and told me that he had contracted a fresh urethritis; "tomorrow," said he, "I shall have none of it, and the day after my knees will be swelled;" and such was actually the case. I have seen a tolerable number of similar cases, in which the articulations were seized immediately on the cessation of the urethritis. I advised them to introduce for some time a sound, and even to moisten it with tincture of cantharides, in order the better to fix the inflammation; this they did, though persuaded it would not have the desired effect, and, in fact, it had not. At that time, I had not established those connexions between diseases, which cause the formation of the physiological physician; if I had, instead of thus uselessly tormenting my patients and myself, I would have made them give up the urethritis to the mouths of thirty or forty leeches applied to the perineum and root of the penis, before it had time to proceed to the articulations, or I would have applied the same means to the latter, in the event of my failing to preserve them in time.

We have said that a visceral phlegmasia may replace urethritis. I have seen a gastro-enteritis supervene in this case, but have also observed that, on its disappearance, the urethritis returned. The same remark applies to colitis and recto-colitis. I have seen one case, in which the irritation of the urethra seemed to be transported to the lumbar portion of the spinal column. It was that of a person who had used astringent injections: he succeeded in suppressing the clap, but got a lumbago in lieu of it: I recalled the urethritis, and the lumbago disappeared; knowing no other instance of the kind, I will draw no conclusion from it. The lumbago was peculiar, in being propagated along the limbs; but there is nothing strange in this, for irritation may traverse the whole body, and cross it in all directions. Be not astonished at any repetition or transfer of this phenomenon, and, above all, avoid the creed that such cases must be rendered special; most frequently they are determined by an individual predisposition.

Urethritis often passes into a chronic state, especially in lymphatic persons in this climate, who have had several attacks of it, and in whom its intensity is not great. It is then extremely obstinate, and when it has continued beyond three months, it usually becomes confined to one point of the urethra, at which it causes a contraction; for it is a law of the inflammation of the mucous canals, that when it becomes chronic it no longer passes over the surface, but becomes circumscribed and confined to a small point, which point it contracts. This you see in urethritis, and all the phlegmasiæ of the internal canal—an important point, particularly as it refers to the inflammations of the digestive canal.

When urethritis attacks a full-blooded subject, and is not combatted, it goes on, extends to the prepuce, produces phymosis or suppuration in it, the penis swells, and gangrene may be feared. When it advances with rapidity, and produces pain of the root of the penis, a cystitis of the cervix of the bladder may be induced, which may itself prove fatal; this I grant is rare, but still I have seen it in men placed in circumstances when the disease is exhibited in its greatest intensity. If the inflammation tends to a descent to the testicles or to a passage to the joints, you have a right to expect serious consequences. The same is the case when ophthalmia succeeds it, in consequence of inoculation, or by a transfer of the irritation without previous stimulation of the eye; both are possible, and therefore no reliance is to be placed on urethritis that is liable to displacement, or rather on the individuals in whom it has this tendency, for, of itself, it has not this character. Returned to its primary situation, we have only to fear its chronicity or concentration in one point of the organ, a sufficiently disagreeable result to the medical man.

Much may be said of the treatment of

urethritis.' Formerly it was treated by antiphlogistics, emollients, and a few local bleedings; and as other symptoms often appeared subsequently, and were attributed to syphilis, mercury was administered. Now-a-days, the inutility of the latter remedy being generally recognised, the main indication has been to combat the inflammation. Some use astringents and narcotics immediately after the appearance of the disease, and these have succeeded when the inflammation commenced in the navicular fossa and was not intense. Others remarking that these astringent injections acted as reperssives, and fearing their consequences, treated it internally with turpentine, tolu, copaiba, &c. Some employ jalap and violent purgatives, and some cubebs, which is highly stimulating; by which means an irritation of the digestive canal is raised, in order to destroy that of the urethra: and terrible are the effects that sometimes ensue. When the cure is effected it is by the general laws of revulsion; but the mischief that may accompany it when thus induced has led some physicians to treat the disease with emollients and sedatives for thirty or forty days, and then leave it to disappear of itself. Another mode is to drink forty or fifty tumblers of water per diem; I have seen others make large injections of water for the same purpose. All these practices have their success and ill consequences; but what are we to propose? Here I think is a case for electism, and I propose the following treatment. At the commencement of the urethritis we may endeavour to remove it by a local bleeding or emollients, and this sometimes succeeds; if it does not, recourse must be had to astringents combined with narcotics, in injection or lotion; in this manner the inflammation is frequently arrested when not too fierce, and if already diminished by antiphlogistics. If advanced in the urethra we employ oily injections, which sometimes put a stop to it in the first instance: watery opiate injections have a similar effect. It is often stopped in two days; but application should be made to it at once, for if it has already existed seven or eight days, is very inflammatory and attended with dysuria, the above treatment no longer succeeds, and should not even be tried. It only then remains to employ antiphlogistics, general bleedings, local bleedings, ice, local emollients, strict diet, and mucilaginous drinks: in case of dysuria or ischuria, leeches to the penis and perineum succeed well, particularly if seconded by demulcent glisters, into which opium and camphor enter. When chronic, we persist in the antiphlogistic treatment until we find it useless.

On the cessation of urethritis and its transfer to the testicles, the inflammation there must be attacked with leeches and ice; as also in hydrocele, even when all pain has ceased: in this manner I got rid of it in a

person who had had it for two years, and had been once tapped for it. In these cases there is always an obscure and indolent inflammatory movement, which keeps up the disease. If urethritis extends to the kidneys, we treat nephritis, of which we make mention hereafter. If ophthalmia supervenes it must be treated energetically, otherwise the consequences may be rapidly serious. If referred to the joints, it should be attacked with antiphlogistics, although in the case I quoted above I removed the inflammation from them by general bleedings, strict diet, a few doses of mercury within, and mercurial frictions on the knees. When urethritis gives rise to an internal gastro-intestinal phlegmasia, it should be combated by the means usually indicated.

This, I believe, constitutes all that is essential to be said on the treatment of this disease. I repeat the advice I gave, to be chary in the use of internal revulsives, as purgatives, copaiba, and cubebs, and to be ever on your guard to avoid the production of gastritis, which may be excessively acute and complicated with arachnitis, as I have seen it in an unfortunate student, whose sufferings, after taking cubebs, were agonizing, and who had nearly sunk under an attack of encephalitis. If some vigorous people bear this treatment, there are others who cannot, and the prudent physician will have a care not to expose them to consequences that may poison the remainder of their lives, if they be not carried off prematurely. I am often consulted by men of fifty, sixty, and seventy years, who have been Herculeses in their youth, during which they had venereal complaints that, having been treated in the dangerous manner I have stated, left behind them internal affections of the heart, the digestive canal, the bladder, &c.—the more fearful in degree, as the practitioners who had produced them did not know how to treat them; we must not celebrate the momentary cure of disease, we must look to the consequences of it.

Vaginitis.—Inflammation may prevail in one part only of the genital mucous membrane, or in its whole extent, from the vulva to the cervix uteri inclusive: in this last limit we consider it. Its causes are more numerous in the sexual organs of women than men, because there are more functions attached to the vagina than the penis: besides the stimulation of cohabitation, there is labour. Add to this, that the female genital apparatus has more intimate and numerous connexions with the skin, the stomach, the lungs, and with all the important organs of the system: that it is provided with a far greater quantity of blood-vessels and nerves than is the male apparatus: and that, consequently, it exerts a much more powerful influence on all the functions, although puberty does not produce such marked changes, and is not manifested with such impetus in the female as in the male.

The great labia, the vagina, and cervix uteri, are undoubtedly very active mucous surfaces, have an infinity of vessels and nerves, and an erectile and exceedingly inflammable cellular tissue: while every month there is a considerable afflux of blood to them, and considerable excitation of them at each coitus. But more than all this, these parts are subjected to all the violence, pressure, contusion, and laceration of labour. We cannot, therefore, wonder that the genital mucous membrane of women should be more liable to inflammation than the urethra of men; the female urethra is certainly less exposed to inflammation than that of men, because the causes of irritation are less numerous in it, but it is nevertheless affected in a similar manner.

In summary of the causes of vaginitis, we have external violence, abuse of coition, the monthly stimulation of the menses, labour, sympathetic connexion with other irritated organs, especially with the stomach and skin.

In this, as in other parts, inflammation is either acute or chronic, confined to the mucous membrane or extending to the subjacent tissues. Its characters are increased redness and heat, a feeling of burning, fulness, and tension, with an augmented secretion of mucus, pain on passing urine, &c. In the commencement the increased mucous secretion does not exist, and is only manifested upon the disappearance of the first onset of irritation. If the inflammation is violent there is swelling, decrease of the calibre of the vagina, and great difficulty in sexual intercourse. If still more intense, and of a phlegmonous character, as is the fact after violence or violation, it is not confined to the mucous membrane, but extends to the substance of the vagina as far as the uterus, presenting the appearance of the most acute phlegmon, in which the external parts participate, as shewn by their turgescence and approach to suppuration; two or three such cases I have seen among troops.

Chronic vaginitis puts on another appearance; the tension and swelling are diminished: there is a flux of thick and opaque mucous matters: on examination the passage is found unnaturally warm, but less palpably so than in the acute stage. Most commonly the phlegmasia is limited to one region of the vagina, but may occupy them all: it most frequently is situated about the cervix, in which event it is confined to the mucous membrane, and produces a discharge called whites.

As regards propagation, it has already been described under the acute stage, for phlegmon is an actual propagation. It may tend towards the uterus, the bladder, the clitoris, the lymphatic ganglions of the groin and surrounding parts—may seize on the rectum, and simultaneously occupy it, and the vagina, and the neighbouring cellu-

lar tissue, though this last is not peculiar to vaginitis, but rather occurs in inflammation of the rectum. Never lose sight of these propagations; the evil of classical works to me appears to be the limitation of the descriptions of inflammation to parts which it very frequently exceeds; it should rather be represented as never in a state of repose, but both able and tending to communicate itself in all directions.

The progress of vaginitis differs according to its intensity: if phlegmonous, it may go on to suppuration and abscess; non-phlegmonous, it goes on like a catarrh. When chronic, it sometimes happens that the inflammation fixes in some follicles, and becomes aphthous, ulcerous, and corrosive: this, however, is rare. For the most part it presents a mass of varieties, that have long embarrassed practitioners. It may be excited by all the causes of superexcitation, change place, and cease suddenly. Cold is the most frequent cause, by suppressing the action of the skin, of the increase of whites, without inducing pain in the majority of instances. Vehement stimulation of the stomach, dyspepsia, the use of exciting fluids, may cause a sudden suppression of the discharge; and so true is this, that practitioners have employed tonics, astringents, and strong wines internally, to obtain suppression, and they have obtained it when the disease was only superficial, and only consisted in a habit of superexcitation, without any true inflammation. The surplus of stimulus inflicted on the stomach then operates as a favourable revulsion, and the discharge, which is only the product of a secretory irritation, yields: such cases are recognised by the absence of pain in the vagina, and a state of debility, rather than superexcitation. When women are under the influence of grief, exposed to cold and ill clothed, the vaginal mucosities may flow in abundance, and give rise to an unnatural condition, that forces the organ to secrete and become a factitious emunctory, like the kidneys or other secretory organs, or like that of the bronchi, which secrete without inflammation, after having suffered repeated catarrhs. Thus limited to the secretory parts and non-inflammatory, vaginitis may augment under the influence of debilitating causes, and diminish or altogether cease on an increase of action in another organ, as when, for instance, the stomach is stimulated by a more generous nutriment, or the lungs respire a purer and more refreshing atmosphere. You may find numbers of females who live in Paris having this discharge, and who are rid of it almost directly after they get beyond the barriers.

The case of stricture, as a consequence of chronic vaginitis, is less common than as that of urethritis. But very many females have a local and permanent point of irritation, some at the cervix uteri, others in the urethra and the anterior sub-pubian part,

where the organ is swelled, whilst the bladder is simultaneously affected, and others, again, in the posterior and inferior parietes corresponding to the rectum; these three cases I have certainly ascertained to exist, and there may be others. When you have to treat a vaginal discharge, you should first be sure whether you have to deal with a habit of mucous supersecretion, or with one of these irritative points, and you distinguish them thus: when the disease depends on a fixed irritation there is no complete remission: tonics do not cure, but rather exasperate it: manual examination discloses the diseased point, and the speculum gives opportunity of seeing it with greater precision, and determining the degree of alteration.

The progress of this chronic stage will be readily comprehended from what precedes. Simple whites may be for a long time supported by women, without any fear from their duration; they get quite well when the menses cease—a fact to which you should attend. These fluxes that go on without apparent phlegmasia, have been considered as passive, yet the period of their cure is that when the womb loses its activity. They must depend on a certain kind of irritation; for, if the organ whence they proceed is in connexion with the head by the influence of sorrow, with the stomach by excess in diet, with the skin by alternations of heat and cold, and with the lungs by various qualities of the atmosphere, as is observed, so as to leave no doubt of the variations of mucous secretion in consequence of such influences—it is impossible to deny that the diseased parts possess more activity than they ought to have; for an inactive organ has no sensible connexions, is not moved in concert with others, and remains indifferent to the disturbances of the system. Look at those fluxes that take place in the intervals of the menses, and appear altogether passive; they disappear at the onset of the menses, and are not mixed with the blood: the fact is, that another mode of irritation takes the place of that which kept them up.

I am altogether unable to assign any limit to chronic vaginitis; all I can say is, that when it is purely mucous, and without disorganization in any point, it goes away on the cessation of the menses, or may be readily cured: that when it depends on a permanent inflammation of the cervix uteri, as this always tends to penetrate into the nervoso-sanguineous erectile tissue of the part, it does not stop unless it be combatted, and may end in metritis; that when it approaches the rectum and bladder, it may produce thereabout, in the acute stage, phlegmonous, abscesses, indurations, and, in the chronic stage, scirrhus, cancer, melanosis, &c. I have treated women who had, at the same time, an inflammation of the vagina, of the bladder, and the rectum, and

who could neither pass urine nor fæces; these parts were red and indurated. They were treated with antiphlogistics, and the inflammation yielded; subsequently, under the influence of stimulants, or of causes which they concealed, it recommenced, until the secretions being suppressed, an inflammation of the whole vascular apparatus took its start from this focus of phlegmasia, and proved fatal. These instances I have seen, and such it is that authorize me in always exhibiting inflammations to you as mutually dependant on each other; you will never get me to describe a disease as isolated: I shall ever show its connexions with others, for I cannot imagine systematic medicine without it. Women never die from the mere vaginal affection, even when induration and ulcers of the cervix uteri supervene. If the inflammation remains confined to that part, they may live for a long time, and it must be propagated to the central viscera to kill them. Those who have ulceration of the cervix uteri, begin by feeling the uterus more weighty, and by being constipated, because defecation is attended with pain; they have a burning sensation, upon which ensue the phenomena of dissemination, or the sympathies, the febrile state, the derangement of the digestive passages; phlegmasia are developed in the abdomen or chest in those so disposed, especially in cold countries. The lungs become gorged and filled with tubercles; diarrhœa replaces the constipation, and the patients sink in the acute febrile state, or die consumptive; the absorption of the pus sometimes adds to the destructive causes.

Regarding the differences dependant on individualities, it is clear that women of the lymphatic constitution, whose menses have ceased, or are about ceasing, have more to fear from tubercular affections, and that the sanguineous are more exposed to purely inflammatory diseases; that, in youth, they who have an affection of the cervix uteri and whites at the same time, in whom you only find, by manual examination, a sensible and smooth tumefaction, and whose menses are otherwise healthy, are only suffering from a curable inflammatory complaint; whereas if you find a body that is uneven and hard to the touch, and the speculum shows you that it is thickened, yellowish and degenerated, you may assert that the disease is incurable, and the female lost, inasmuch as the chronic irritation has produced tubercular, lardaceous, encephaloid, or other alterations; this is often the case when you are called to examine a woman of forty-five to fifty-five years of age, whose menses no longer flow. Such are the foundations of your prognosis, and also of the pathological anatomy of the disease.

Acute vaginitis may be subdued by local bleedings; general ones are rarely called for, unless there is visceral complication and congestion. Emollient injections do not

succeed in the first instance. It is for the most part erroneous to persist in injecting into hollow organs in a state of inflammation, of pain and resistance to distension; this applies to the rectum as well as the vagina. But when the inflammation is diminished, such injections, cold or scarcely tepid, may prove useful. Rest must be enjoined. If there is heat, as is the case in women of irritable temperament, baths, and emollient and sedative topical applications should be prescribed, cooling glysters, &c.

If it is chronic, the treatment is more difficult: here I shall refer to my three former distinctions;—1. If it is only a simple mucous irritation, spread equally over the surface, and you ascertain this by the suppleness, absence of heat, and plumpness of the parts touched by the finger, by the absence of swelling of the cervix, it is only whites, such as are met with most frequently in lymphatic females. Then examine the digestive canal: if it is inactive, give stimulants, generous food, and astringent preparations. To guard against relapse, make your patient wear flannel: you never can obtain equal benefit from a vehement stimulation of the stomach, by sudorifics, as from the constant application of flannel to the skin, and you may injure the stomach by forcing periodical sweatings. When the discharge depends on the quality of the atmosphere, and the patient is affected with it in town and free from it in the country, recommend the latter habitat, with frictions of the skin, and temperance in, or abstinence from, coition. 2. If you have to combat a predominant point of irritation, the matter is more serious. Should this point be in the urethra, or along the rectum, you have a cystitis and rectitis to treat at once. But the cervix uteri is the most common seat of obstinate whites, and this affection exhibits various indications according to its degree and nature. The cervix being only superficially hardened, and not much swelled, and without great increase of heat, the complaint is not serious, even if some small excoriations are added. This kind it is that may be treated as strictures of the urethra are in men, and cauterization is necessary. But when the ulceration is not seated in a yielding tissue, but in the midst of deep induration, the case is important, and you should pursue your examination further. If, on raising the uterus with the finger, the hand being applied over the hypogastrium, you feel the uterus heavier and larger, I do not think you ought to apply caustics: I have never seen it succeed. In extirpation I have no faith, when the induration is deep, smooth, lardaceous, and appears on the cessation of the menses; if then practised you behold the consequences in scirrhus, metritis, or peritonitis. I have certified the evil effects of caustics and the knife on all occasions when the inflammation and induration ex-

tend beyond the cervix. My profession of faith here is, the antiphlogistic treatment in the first instance; if it does not succeed, and the excoriations on the cervix are only small, slightly indurated, and red, cauterization may cure, and ablation also: but the latter is useless, or should not be undertaken until you have found the insufficiency of the former, and the limited alteration of the cervix; for if you do not cut into sound parts, you operate in vain, and only accelerate the progress of the disease, and the exit of your patient. In short, you must here, as in every other affection, proportion the means to the extent, the duration and standing of the disease, and the constitution of the patient. 3. For the incurable cases, in which there are deep ulcerations and excavations, you can neither attack them with caustic nor operation; you have only the palliative treatment. I find that I have not mentioned leeches to the cervix; they are very useful when the disease is only superficial inflammatory, and the excoriations slight, but not when there is deep ulceration, a lardaceous state of the part, and ulceration. Even in these cases they may afford some relief; but, on the other hand, may cause serious hæmorrhage. At all events they are safe in the commencement. Some say their bites ulcerate, and lead the way to the destructive process; but this is an exaggeration—ablation and cauterization often produce worse consequences. To return to the incurably ulcerated cases: if the viscera are affected, they must be treated, but not always, with equal energy. I suppose a young, robust person affected with irritation of the uterus, to which is added a gastritis, pneumonia, &c.; such a case you will do well to combat with general bleedings and leeches: but should it happen in a lymphatic woman long afflicted, and in whom you have reason to suspect an advanced induration and degeneration, of what use will it be to exhaust her with bleeding, when cough supervenes, or with leeches when the stomach is deranged? There is a *medecine de capitulation* which I distinguish from the curative, and which the physician employs when he finds himself worsted. He is bold so long as he knows it is possible the disease may yield: but when no hope remains, he becomes cautious; and, being no longer able to subdue, he moderates or soothes the disease. Then it is that emollients, narcotics, and mild diet should form the sole treatment, and not an active medication: at the same time, attention should be paid to the *morale*, and all disturbing causes avoided.

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN.

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;*

Session 1834-35.

LECTURE XLV.

*Diseases of the Intestinal Tube developed after
Birth—Intestinal Indigestion—Invagination
of the Intestines—Enteritis—Follicular—
with Disorganization of Tissue—Entralgia
—Spasms of the Intestines—White Ramol-
lissement of the Gastro-intestinal Mucous
Membrane.*

GENTLEMEN—The intestinal canal is liable to irritation, spasm, and pain, independently of inflammation, in the same way as the stomach. We meet with intestinal indigestion, invagination, griping and spasm, or entralgia. These disorders of function may occur in any part of the intestinal tube, independently of inflammation; but when long continued, they may induce the last disease, when the usual symptoms of enteritis will present themselves. Improper food, and exposure to cold, are the commonest causes of intestinal derangement. The gripings and colics of infants are generally to be ascribed to these causes. The symptoms of these disorders are worthy of attention.

Intestinal Indigestion.—A vast number of infants at the breast suffer from diarrhoea, become pale, blanched, and emaciated; they gradually perish, and on examining their bodies, we cannot find a single sign of inflammation. The infants thus affected die from want of nourishment, they really die of hunger, their stomach and intestinal tube do not digest the milk which they suck or drink. Let us examine the symptoms and causes of this intestinal indigestion. The symptoms are progressive emaciation, paleness of the countenance, continual hunger of the infant, who seizes the nipple with extraordinary avidity whenever it is applied to the breast. There is a discharge of mucosities from the bowels, often mixed with coagulated, or curdled milk. The infant may perish before it is greatly emaciated, and we generally find, on examination of the intestinal tube after death, a general redness of a part or the whole of the canal; or it may be inflamed, ulcerated, or sottened. M. Billard states, that in 1826 he examined the bodies of fifteen infants, aged from fifteen to thirty days, who were affected with chronic diarrhoea without inflammation. In eight of these, he found no lesion; there was a general decoloration of the integuments of the intestinal tube, and all the

organs were exsanguine. These infants never ceased to vomit and to have purging during life; and in some the abdomen was tympanitic. In others there was a greenish matter in the colon, somewhat similar to meconium. The decoloration is a species of ramollissement. In some cases there were patches of congestion, so that the surface of the intestinal tube was not entirely white. This decoloration is supposed to result from inanition or want of aliment, and not from inflammation. It closely resembles the decoloration of the stomach and intestines of those who have died of hunger, as described in my own and other works on Medical Jurisprudence. This is also confirmed by a striking fact afforded by the Foundling Hospital of Paris. In that establishment, a vast number of infants perish from want of nourishment. The infants are generally suckled by sedentary nurses, who have been delivered so long, that their milk is unfit for the very young infants committed to their charge. They also change the infant every week, and give their breast indiscriminately to every infant presented to them. They pay no attention to the hours for suckling, do not consider the quantity of milk necessary for infants of different ages and constitutions; so that there is too little or too much given, the infants are disordered, and very often perish. Reflecting on this practice, on the carelessness and inhumanity of strangers towards unfortunate infants left at Foundling Hospitals, there are many statesmen and physiologists who have arrived at the conclusion, that these institutions do more harm than good, and that they encourage immorality and greatly increase the mortality of mankind. I shall not stop to examine the accuracy of this conclusion; but I cannot help observing on the baneful effects of errors in the physical education of infants, and how these are diminished by maternal lactation and solicitude. On a former occasion, I adduced unanswerable arguments to prove that every woman in health is morally bound to nurse and manage her infant. But to pursue the pathology of the intestinal tube: I have to direct your attention to some other diseases of this important portion of the animal economy.

Inflammation of the Intestines—Enteritis.—The mucous membrane of the intestines is subject to the same inflammations as that of the stomach, œsophagus, and mouth, which I have already described. It is right to state that one of the varieties of enteritis, namely, that with alteration of secretion, is very rare, according to the observations of that unequalled infantile pathologist, M. Billard.

This author has described enteritis during intra-uterine life, in some examples accompanied by excrescences or vegetations on the duodenum, and in chronic colitis. Such inflammations are, however more frequent after birth.

Inflammation of the Intestinal Tube developed after Birth.—Inflammations of the intestinal canal may be divided into four varieties: 1. Erythematous enteritis; 2. Enteritis with alteration of secretion (muguet); 3. Follicular enteritis; 4. Enteritis with disorganization of tissue.

1. *Erythematous Enteritis.*—There is scarcely any difference between passive congestion of the intestinal tube and erythematous inflammation. The first is the precursor of the second. In the latter there is ramiform or capilliform injection, there are red patches of a greater or less extent, situated in the most dependent, or in any other portion of the intestinal tube, accompanied by a tumefaction, or greater or less friability of the mucous membrane. The disease may attack infants of one day old, or at a more advanced period of life. In forty cases detailed by Billard, the infants were from one day old to a year. In thirty there was diarrhœa, with yellow liquid motions: in six, the drinks were vomited; in twenty-five there was tympanitis; in four the motions were natural; in six there was no diarrhœa; in five there was an erythematous redness about the anus, caused by the irritation of the alvine motions; in all, the skin was remarkably dry and hot; in four only was the pulse febrile, and these infants were from five to twelve months old; and in twenty-five there was a particular expression of countenance, characteristic of severe suffering. In some there was profuse intestinal hæmorrhage, and the blood exhaled from different points of the tube. One infant vomited blood, and also passed it by stool. The disease may also be complicated with pneumonia or cerebritis, or with intense inflammation of the brain, its membranes, or with that of the lungs.

On examining the bodies anatomically, we find intense redness, a brownish coloration, various spots or red lines in different parts of the intestinal tube, more especially in the ileum and colon.

This form of enteritis is generally complicated with gastritis, and the symptoms of both diseases are well marked. These are constant vomiting, heat of the abdomen, pain on pressure, the lower extremities drawn up, the bowels very much confined or very much relaxed, the motions depraved. It is, however, consoling to know, that the treatment of enteritis, or gastro-enteritis, is the same.

2. *Enteritis with Alteration of Secretion, or Muguet of the Intestines.*—This has been rarely observed in the ileum and colon, and is of very rare occurrence. The treatment is the same as for the other varieties of enteritis.

3. *Follicular Enteritis.*—The follicular apparatus of the intestinal tube may be, like that of the stomach, the seat of the disease. It consists in a number of small isolated glands in the first two thirds of the small intestines, which are formed into groups in different parts of this canal. These follicles

are isolated in the larger intestines—the cœcum, colon, and rectum. They may be more or less apparent, though, in some infants, they are scarcely discernible.

They undergo changes that are not inflammatory. At the period of dentition, their function of secretion may be very much increased; they may be enlarged and more prominent than usual; but, nevertheless, they are not red, inflamed, or ulcerated. M. Billard observed twelve cases of this description.

There were three of the affected infants aged from eight days to three weeks, two of two months, seven from nine months to a year, and these were commencing their first dentition. Ten of these had a profuse thin diarrhœa, which was in direct relation with the development of the follicles, and the increase of their secretion. The greater number of the infants were teething, so that we perceive a remarkable connexion between the appearance of the first teeth and the development of the follicles in the intestines. It is easy to explain this physiologically. The follicular apparatus is intended to assist digestion, and its development progresses with that of the teeth. Nature has, therefore, fixed the same period for the development of all parts of the digestive apparatus; and it is for this reason that the salivary glands increase considerably, and secrete an abundance of saliva at the commencement of dentition. This coincidence in the normal development of the teeth, salivary glands, and follicles in the intestines, and the direct sympathy between all parts of the digestive tube, enable us to explain the relation that exists between dentition, salivation, or drivelling, and the watery diarrhœa, which so often affects young infants during dentition. Thus there is a functional and morbid sympathy, as well as a coincidence of development. M. Billard is of opinion, that it is the excitability of the muciparous glands which causes the augmentation of their secretion, and that they are in an intermediate condition between the normal and inflammatory; and, therefore, that attention ought to be paid to the regimen of infants affected with this thin watery diarrhœa. Emollient drinks, as milk, barley water, gum arabic dissolved in water, will be administered with benefit in this species of diarrhœa. This disease causes debility and emaciation in a few hours, and sometimes even death. In some cases there will be thirty or forty watery motions in twenty-four hours, and unless powerful astringents are frequently and speedily exhibited, the disease will prove fatal. The treatment will be fully described under the head of Diarrhœa; but I may now observe, that leeches and fomentations to the abdomen are necessary, notwithstanding the apparent debility of the infant. This plan is the more necessary, as it is often difficult to distinguish follicular from the other varieties of enteritis during life in young infants. In those about

the seventh or tenth month, the disease produces those symptoms which MM. Serres and Petit have described as characteristic of entero-mesenteric fever, and M. Bretonneau has termed *dol-inenterite*.

Inflammation of the follicular apparatus in adults causes all the symptoms of typhous and adynamic fever; but this is not the case in young infants, though with those that are more advanced in life.

In fine, this variety of inflammation may become chronic, but rarely in infants at the breast. It also supervenes in mesenteric disease, and in tubercles in the lungs.

4. *Enteritis, with Disorganization of Tissue.*—The commonest disorganizations of the intestines are inflammatory ramollissement, and gangrene.

When the mucous membrane has been a long time inflamed, it acquires a degree of friability which enables us to separate it with the nail, and it loses all the characters of its structure. It falls off in a soft reddish mass when we attempt to separate it from the subjacent tissue. There are no distinctive symptoms of this disease, and it cannot be distinguished from other varieties of enteritis during life.

There is another kind of ramollissement, which is termed white, to distinguish it from the inflammatory. It is observed in those infants which are badly fed, who become pale, blanched, and emaciated before death. In these the mucous membrane of the stomach and intestines is found pale and discoloured, similar to the external integuments. The membrane is, however, softened, as in the inflammatory ramollissement, though of a white colour.

Gangrene of the intestines is most commonly observed near the ileo-cæcal valve. It appears as a dark spot, which speedily sloughs and forms a complete perforation of the intestine, which allows the fecal matter to pass into the cavity of the abdomen. This rarely happens in infants at the breast, but is frequently observed in those of a more advanced age. There are no symptoms except the ordinary ones of enteritis, by which we can distinguish intestinal gangrene. It is also very difficult to distinguish, in young infants at the breast, between inflammation in the different portions of the intestines, though M. Billard has attempted the diagnosis, and termed inflammation of the duodenum and the rest of the small intestines, enteritis or ileitis; and that of the large intestines he designates colitis. He gives a report of several cases, which deserves careful consideration. In eighty cases of inflammation of the intestinal tube, there were thirty of entero-colitis, thirty-six of enteritis, and four of colitis. In the thirty cases of entero-colitis, there were twenty in which the infants were affected with diarrhœa, the motions being yellow or green; in the ten others there was no purging. In all there was tumefaction of the abdomen,

and pain on pressure. There was vomiting of a yellow fluid in twelve, though there was no gastritis. In all there was erythematic redness about the anus, caused by the contact of the alvine motions. The tongue was red and dry, the skin very hot and arid, but the pulse was not raised, and sometimes was feeble.

In thirty-six cases of inflammation of the small intestines there was vomiting of drink or fecal matter in twenty, and in fifteen the disease was situated near the ileo-cæcal valve. The tumefaction of the valve offered an obstruction to the passage of the fecal matter, and gave rise to the vomiting of it. The abdomen was always tumefied in the commencement or course of the disease. In twenty-four there was diarrhœa with greenish motions like meconium, the tongue was red, the skin hot, and the pulse slightly affected.

In the fourteen cases of colitis, there was diarrhœa, the swelling of the abdomen was more or less considerable; six of the infants vomited, and very generally the integuments were cold and livid. The pulse was scarcely affected. It is remarkable that the pulse is greatly accelerated in enteritis of adults, and there is also intense fever.

Most of the eighty infants whose cases were examined, were aged from one day to six months; and a few from six months to a year old.

It follows, from the facts thus adduced, that it is extremely difficult to form a diagnosis in enteritis of infants at the breast; though it appears that rapid tumefaction of the abdomen, purging and vomiting were present in enteritis or ileitis, whilst in colitis purging alone without tumefaction of the abdomen is more frequent.

The complication of gastritis and enteritis is extremely common in new-born infants, and the symptoms already enumerated enable us to distinguish this complication. These, however, differ from those of the adult, as already stated.

Symptoms.—The symptoms of diseases of the digestive organs in nascent or new-born infants are almost always local; they seldom excite constitutional disturbance or fever, as in adults, unless when the infants advance in age. Let us endeavour to analyse the symptoms, so as to distinguish the inflammatory diseases of the intestines. There is vomiting in enteritis of a yellow matter, but it does not happen on taking drinks. Diarrhœa is almost always present, and it is generally watery or serous. This is caused by an augmentation of secretion in the follicular apparatus. Tympanites and tension of the abdomen, with pain on pressure, are the distinctive and almost constant signs of enteritis. If we add to these the redness and dryness of the tongue, the heat of the skin at first, and afterwards its coldness and lividity—in fine, the erythema of the anus and surrounding skin, we have the

most common symptoms of gastro-enteritis, of enteritis, and entero-colitis. When these diseases become chronic, the infant emaciates, and its bones become prominent, the countenance is changed, the appetite is lost, there is a desire for cold drinks, the features are sharpened, and the infant picks its nose and lips.

Some infants are peevish and feverish for several days, or even three or more weeks, having the preceding symptoms, which are ascribed by some practitioners to teething, or worms; and the disease is termed infantile remittent fever by authors. It is most common in children from one to seven years of age, and is of almost daily occurrence. You observe numerous examples of it at the Free Hospital, and at the Western Dispensary. Let us investigate the causes.

Causes.—The vascularity of the intestinal canal, before and at birth, is very great, and is readily increased by any derangement in the circulation in the chest or abdomen; and also by the administration of aliment which is too hot, exciting, and difficult of digestion. Such are the causes of abdominal inflammation in new-born and young infants. These causes are in almost constant operation, especially the errors in diet, and therefore their effects must be as constant. Thence it is, that of all the diseases of infants, those of the digestive organs are the most numerous and fatal. It is on this account that I so minutely described the alimentation or food of infants and children; and it is for the same reason that maternal lactation and care are strongly advised by physicians.

Treatment.—The indications of treatment are drawn from the preceding history. We have seen that sanguineous congestion is the primary cause of inflammation of the digestive tube. This is to be diminished by warm bathing or fomentations, with two or three leeches applied to the abdomen or round the anus. The latter part is preferred by continental practitioners, as leeches to it more directly relieve the abdominal vessels, on account of the connexion between them and those of the lower bowel, than if applied on the abdomen. We thus relieve the congested state of the mucous membrane of the alimentary canal, by leeches, and the warm bath, which determines blood to all parts of the body, and consequently diminishes it in that part in which it is in excess, which is the case in all congestions and inflammations. We next direct our attention to the inflamed surface. We order abstinence from food, or at least diminish the quantity, and therefore advise that the infant ought to be but rarely applied to the breast. We prescribe for it mucilaginous drinks or barley water, sugar and water, mucilage or gum arabic dissolved in water, &c. But as the infant cannot bear the want of nourishment for any length of time, we order it starch clysters, with chicken or beef broth, and two or three drops of lau-

danum. There is great caution required in using opiates in clysters, as infants are readily narcotised. A clyster composed of two ounces of starch, with one of broth, and two or three drops of laudanum, will be sufficiently powerful for infants under a year old. When the infant is older, our treatment should be more energetic. Many practitioners exhibit aperients, and almost entirely depend upon them in gastro-enteritis; but they should be used with caution.

Those who have not studied the pathology of infantile diseases are too much in the habit of prescribing for names and not for actual disease; and we have ample proof of this, by referring to the first and last edition of Underwood's work, in which we find such diseases as inward fits, watery gripes, &c.—mere words without a pathological meaning.

Besides the inflammations now described, the intestines are liable to spasms, which cause griping, choleric, intussusception or invagination, and many other diseases. These I shall now proceed to notice, in the order of their frequency.

The modern pathologist will find many of them symptoms of morbid lesions; but as they are described by the most popular writers and lecturers on diseases of children, as diseases, I shall follow their example, more especially, as I have given the pathology of the digestive tube according to the latest and best authorities. It cannot be expected that the public or the profession will abandon the errors of popular writers, and therefore we must notice them.

Retention of the Meconium.—The mucosity contained in the intestines of the infant during pregnancy is mixed with bile, as proved by chemical analysis, and is of a dark green or black colour. This fluid is probably intended to prevent the obliteration of the intestinal canal, which it lubricates. In a short time after birth, as soon as respiration is fully established, the pressure of the diaphragm and abdominal muscles on the intestines excites their peristaltic motion, which expels their contents—the meconium or dark green fluid. When the infant is subjected to strong uterine contractions during parturition, or when it comes into the world by the breech or feet, the meconium, or first alvine defecation takes place, sometimes in the uterus or vagina, or immediately after birth.

When this fluid remains for any length of time in the bowels of a new-born infant, its thinner parts are absorbed, and the remainder becomes thick and tenacious. The chief cause of its retention after birth is supposed to be spasm of the sphincter ani. Tissot maintained that this spasm was excited by the action of the air on the skin. The tenacity or viscosity of the meconium, or its adherence to the intestine, may prevent or impede its evacuation, when the bowels are not stimulated by the colostrum, or first milk of the mother. In fine, we

observe that infants who are naturally feeble, who suffer in the birth, and who want proper care afterwards, void the meconium with great difficulty.

If the mother has breast-milk, and applies the infant in a short time after birth, her first milk, called colostrum, will purge it, and no aperient is necessary. It is held by some writers that new-born infants do not require purgatives, no more than the young of other animals, and may be left to nature. The inferior animals live more in accordance with nature's dictates than mankind, who are involved in artificial conditions. It is true that the meconium is often expelled by nature, but when it is retained, or when the infant is spoon-fed, or is suckled by a mother whose milk is not well elaborated, or by a nurse whose milk is several weeks or months old, an aperient is necessary. When the meconium is not voided in a few hours after birth, though the breast milk has been given, or when there is no milk, the infant is griped and deprived of sleep, it is then necessary to employ some mild aperient, as almond oil, castor oil, manna, honey, treacle, soft sugar, syrup of violets, or syrup of chicory, which is composed of rhubarb. Dr. Harris recommended a watery infusion of rhubarb, properly sweetened, in preference to the common oils and syrups in general use. When these fail, syrup of buckthorn is advised, but this is seldom kept, and compound tincture of aloes sweetened, is usually substituted for it. Dr. Hamilton, of Edinburgh, increased the dose of syrup of buckthorn to an ounce, and discovered that it was the aloetic tincture which had been substituted for it. This dose would be too large in most cases, but some will require it. Dr. Underwood prescribed the following medicines in the course of thirty-six hours, for an infant of thirteen days of age, which was constipated from birth: "two ounces of common infusion of senna; two drachms of Rochelle salts, four grains of jalap, and a grain of calomel; besides purging clysters and the use of the warm bath. The next day the child took four grains of ipecacuanha at two doses, and forty drops of vinum antimonii, at four times, (in the course of an hour) without any effect; and at another period, six drachms of castor oil, besides several doses of manna." When the preceding medicines fail, it will be advisable to alternate them with repeated doses of calomel, which may amount to two, three, or four grains in obstinate cases. But in the majority of instances, a grain of this medicine, with two of aromatic powder, and some honey or sugar, followed in two or three hours by the administration of a teaspoonful of castor oil, will efficiently act on the bowels.

Purgatives may be varied according to circumstances. An infant may be naturally strong or robust, feeble or delicate, sensitive

or nervous. The same medicine is therefore improper in all cases. The good sense of the practitioner, and his knowledge of therapeutics, will guide him in the selection.

Constipation of New-born Infants.—When an infant is constipated, its stomach becomes hard and distended with wind or gas; it cries, draws up its lower limbs towards the abdomen, or is constantly kicking, is deprived of sleep, or screams in its sleep; it is griped and affected with colic, or enteralgia, which may induce convulsions. These symptoms may be speedily followed by inflammation of the bowels, and death. It is therefore necessary to open the bowels as soon as possible, by some of the medicines mentioned for the expulsion of the meconium, and if these fail, by clysters, or suppositories of soap, or cocoa butter. The griping, or "pinching of the bowels," as it is popularly termed, is caused by colic, spasm, or cramp, and this extends to the sphincter ani, or that muscle whose use is to close the anus. To remove this spasm, warm flannel should be applied to the abdomen, or gentle friction made all over the stomach and bowels with the hand made warm; and if these fail, a warm bath will be advisable, as it often acts most efficiently as an antispasmodic and laxative. It was strongly recommended by Hoffman, Tissot, Capuron, and others, and very generally employed in all countries.

Confinement of the bowels and griping of the infants are caused by the breast milk, or artificial food; and the nurse should be particular in her diet, and follow those precepts already mentioned for her guidance. If artificial food be the cause, it should be changed.

Constipation is either constitutional or accidental. If the mother or father should be constipated, so will the infant which most resembles either of them. Some infants are, therefore, constitutionally predisposed to confinement of the bowels, and these very often thrive most remarkably. It is unadvisable, according to Dr. Underwood, to attempt to counteract this habit of body, when the child appears perfectly healthful. He attended many families whose infants were habitually costive, all of whom he states, grew up strong and healthy. He mentions this fact, not to induce practitioners to shew less attention to the regularity of the bowels of children, but that no alarm need be entertained, in cases in which infants pass several days without a motion.

I cannot bear testimony to the accuracy of the preceding statement, and must remark, that I have very often succeeded of late in correcting habitual costiveness by alterative doses of mercury, such as the one-twentieth of a grain of calomel with two grains of rhubarb, one of aromatic powder, and five of sugar, administered every night or alternate night, and continued for three or four weeks. This plan is also successful

in the constipation of adults, as is amply proved by the cases related by Dr. Wilson Philip, in his work on *Minute Doses of Mercury*, and by my own repeated observation. I am now attending a lady, aged twenty-six years, the mother of two children, who has suffered from obstinate constipation for the last ten years. The infant of this lady was of a constipated habit, though it took one of the following powders two or three times a week, and the dose was increased in proportion to its age and strength.

Rx. Hydrargyri submur., gr. j;

Sachari purificati, 3j;

Pulveris rhei, ʒij;

Pulv. cinnam., comp. ʒss.

Tere intime et in chartulas xx divide, quarum capiat unam alternis noctibus.

The constipation continued until the infant was a year and a half old, when its bowels acted every day, and the motion was of a healthy colour. This and many other cases have convinced me of the efficacy of this mode of practice; and I am very much disposed to doubt that infants who are constipated for four or six days at a time, and continue in this state until the age of childhood or puberty, can be in perfect health. In addition to the powders just mentioned, we may use other purgatives; and, it appears to me, that Underwood and other writers have erred in excluding mercurial preparations in their prescriptions for children. The late Dr. Joseph Clarke, of Dublin, very strongly advised half a grain of calomel to be given every night or every second night to infants when troubled with green motions and griping; and he observed that, in the course of a week or two, the stools became natural, and that it was rarely necessary to exceed four or five grains (*Mem. of the Royal Irish Acad.* vol. vi.) Others give two grains of mercurial pill. Dr. Heberden, in his *Epitome of Infantile Diseases*, very judiciously remarks—"Costiveness is not to be desired, nor yet to be dreaded. Too lax bowels indicate a weak, and too confined a strong constitution. The mean is to be observed, if possible; and if any infant should exceed thirty-six hours without a motion, medicine must then be employed." This is an excellent precept for the management of the bowels of infants, but, like all general rules, is liable to exceptions, as the cases recorded by Dr. Underwood amply prove. The physiology of digestion teaches us that the ingestion of food is necessary several times a day, and that the excrementitious parts ought to be expelled daily at least, and not accumulated in the bowels. If these remedies be so efficacious for adults, they cannot be useless, and, I am fully convinced, are not injurious in cases of children. If one of the powders given at night does not operate, we may exhibit a drachm or two of manna, of syrup of senna (the infusion sweetened), or of roses; and any one of these may be mixed with tea, milk, or other drink. In

obstinate cases, from five to thirty drops of tincture of jalap, compound tincture of senna, or compound tincture of aloes may be added. I have repeatedly given a drachm of each of these tinctures in three ounces of water, sweetened with sugar, and in repeated doses, to infants under six months old. Manna and magnesia were once very favourite remedies, and are still very extensively employed. A small piece of manna, about the size of an almond, will be sufficient for an infant during the first year of its age. There is an advantage with this medicine, that children of two or three years old will eat it with avidity. A few grains of magnesia, the calcined or common, or as much as will be raised on the handle of a teaspoon, may be mixed with milk or tea, and sweetened with manna instead of sugar, and given to infants of one or two years old. Parents often give them senna tea, or infusion, with milk and sugar to disguise it. This is a safe opening medicine, but some grated nutmeg, cinnamon, or ginger, should be added to senna leaves when put into the tea-pot or other vessel, before the water is added, to prevent griping. Rhubarb is not a fit purgative for infants of a costive habit, either alone or combined with calomel or magnesia, as it tends to confine the bowels. It is, however, a valuable purgative so combined, when there is a tendency to diarrhoea or bowel complaint. It is apt to gripe, unless nutmeg, cinnamon, or ginger powder be added to it. Castor oil is one of the best and safest purgatives, but its effect is transitory. The alterative powders already mentioned should be given before its administration. A quarter of a grain of ipecacuanha, or three grains of aloes, have been advised. If these medicines fail, we should have recourse to clysters or lavements. A wine-glassful of barley-water, thin starch, or beef-tea, with a tea-spoonful of castor oil, or from five to twenty grains of socotorine aloes, and if this fail, the same quantity of compound tincture of senna, will in general succeed. Suppositories, or dry clysters, are also useful, though too seldom employed in this country. These are made of a slip of paper, or piece of linen twisted, moistened with oil, and introduced into the bowel. If these fail, a small piece of Castile soap, red beet, mallow root, parsley stalk, or common candle may be used.

But the use of purgatives, clysters, or suppositories may, in most cases of habitual costiveness of infants, be superseded by rubbing the stomach and bowels with the warm hand or a piece of flannel, for ten or fifteen minutes, whenever an evacuation or motion is desired.

The continental practitioners employ frictions, with purgative tinctures over the abdomen; and Dr. Merriman has found the following, used for five or ten minutes, effectual: compound soap liniment, one ounce; compound tincture of aloes, half an ounce.

There is abundant evidence, that purga-

tives, tonics, mercurials, and other medicines, produce their usual effects when rubbed on the skin, or, as the ancients termed this method, the *iatreptic*. Modern experiments have, however, determined, that medicines act more energetically when the cuticle or epiderm has been removed by a blister; and the efficacy of this plan has given origin to a new treatment, which is much used on the continent, and denominated the *endermic* method, which means the action of medicines through the derm or skin.

Some nervous infants suffer from tenesmus or needing, and make frequent ineffectual attempts to evacuate the bowels. They suffer so much pain on passing a motion, that they frequently cry, and are sometimes thrown into convulsions. This pain being frequently repeated, the child is afraid to go to stool, the lower bowel becomes torpid, and costiveness is induced. In some cases the suffering is so great, that the child can only be induced to evacuate the bowels when half asleep. A proper dose of the sedative solution of opium, hyoscyamus, or morphia, is the best remedy in such cases, regulating the bowels, and encouraging regular attempts after breakfast, or at a certain hour, to procure a motion. Ascarides or small thread-worms in the lower bowels often excite tenesmus or frequent desire to go to stool, and ultimately give rise to this form of constipation.

There is another kind of constipation caused by intussusception or invagination of the intestine.

Intussusception — Invagination. — This disease consists in a certain part of the bowel affected with spasm, being forced into a portion of the tube below or above it, which obstructs, irritates, and finally inflames this portion of the intestinal tube, and causes obstinate costiveness which defies purgatives, excites vomiting of fecal or bilious matter, and produces mucous diarrhœa, tinged with blood. The causes of intussusception are severe diarrhœa, drastic purgatives, which produce much griping, as senna leaves boiled in water, without the addition of ginger or cinnamon, offensive matter in the bowels, worms, flatulence, or the gases secreted in the alimentary canal.

This disease often causes inflammation of the invaginated portion of the bowel, which speedily mortifies, and is expelled by the rectum. A portion of intestine, which measured several inches, has been expelled in this manner in the adult. But this seldom, if ever, occurs in the infant. In this case, the obstructed bowel rarely yields to purgatives, though an enema or clyster may bring away some fecal matter from the large intestines below the obstructed part. As the disease continues, it excites several other invaginations. Dr. Burns found forty-seven in one case, and his brother, Mr. Allan Burns, met with fifty examples, which caused fatal

diarrhœa. The abdomen rapidly swells and hardens, often in an irregular manner, so that the convolutions of the intestines are perceptible externally. Vomiting and colic supervene, and, in the adult, there is fixed pain in the abdomen; sometimes there are mucous, bilious, and stercoraceous vomitings, and the contents of the bowels above the obstructed part are expelled by the mouth. After a short time, prostration of strength or great weakness comes on, the limbs become cold, convulsions or coma supervene, and death speedily ensues. On dissection, we find several invaginations ascending and descending into the intestine, and sometimes the strangulation is produced by bands or false membranes, the results of inflammation existing between the affected parts, omentum and convolutions of the bowels. The intestine is compressed or strangulated by these bands; in other instances, the intestine is twisted or contorted on itself, forming a knot, which is rendered firmer or more strained, as the adjoining portion of the bowel increases in size from the distention caused by the evolution of gas, or as it is erroneously termed, flatulence, or by the drink or clysters administered to the patient. The infant is relieved by the expulsion of this gas. Invagination may occur unaccompanied by constipation. I have often observed such cases; and, on dissection, numerous invaginations, both upwards and downwards, existed in the intestinal tube.

The treatment of this disease is seldom successful. We endeavour to establish the function of the bowels by aperients and clysters, frictions on the abdomen, warm baths, and according to some, by emetics. This disease, which is of frequent occurrence in young infants, very generally proves fatal. It is not decided whether the intestinal tube of infants is liable to *ileus* or *niserere*, though I see no reason why it should be exempt.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from page 792.)

Strictures of the Urethra. — The commonest result of urethritis is stricture, or obstruction in the urethra, which is a most annoying, and in the end, a most dangerous disease.

The term stricture has been applied to a narrowing of a certain portion of the urethra, of a greater or less extent, induced by inflammation; and as gonorrhœa is the most violent and frequent inflammation of the urethra, it is the most common cause of contraction or narrowing of that canal. This inflammation having lasted in an acute state for a longer or shorter period, becomes chronic, fixes itself upon a certain point of the canal, and gives rise to thickening, indurations, accidental tissues, and adhe-

sions, which obstruct more or less completely the flow of urine. Thickening of the mucous membrane causes a great number of contractions; induration of the cellular tissue, and the surrounding corpus spongiosum, accidental tissues, false membranes and adhesions, which form bands or bridles across the canal, also gives rise to caruncles and carnosities.

The causes of stricture are therefore engorgement of the mucous tissue, induration, adhesions of the parietes of the canal succeeding to ulceration of the mucous membrane, and inducing a more or less perfect septum, which authors have denominated valvular or bridle stricture; carnosities, or excrescences projecting into the canal, callous ulcers, situated in the lacunæ of the urethra, tumefaction of the verumontanum, enlargement and fungosity of the prostate gland, and lastly, concretion in this gland or some part of the urethra.

Various classifications have been given of strictures. In this country it is generally considered that there are three species of stricture: the permanent, the spasmodic, and the inflammatory.

The permanent stricture is caused by thickening of the urethra, induced by chronic inflammation. The spasmodic arises either from contraction of the muscles surrounding the urethra, or according to some, from that of the urethra itself; and the inflammatory is caused by an extravasation of an adhesive matter between the corpus spongiosum and surface of the urethra.

The permanent stricture may be divided into six varieties: that caused by septum, bridle, or valve; the callous, or irregular, in which a greater or less extent of the urethra is found contracted, and the sub-mucous and spongy tissues are indurated; the ulcerative with carnosities and vegetations; the varicose, which depends upon the enlargement of the veins of the sub-mucous cellular tissue, according to Ducamp one of the best French writers on the subject. Stricture is also caused by engorgement succeeding acute inflammation, by induration succeeding chronic inflammation of the parietes, by membranous septa, or bridles, or bands; and lastly, by carnosities. According to Sir Astley Cooper, gonorrhœa is the commonest cause of stricture in ninety-nine cases out of a hundred; though he admits it may arise from external injury. It is often caused by excessive venery, and also by masturbation.

It may be seated in any part of the urethra, from the orifice to the vesical extremity of the prostatic portion; it is generally seated, however, about four or five inches from the orifice, and next in frequency, in that portion of the canal near to the bladder. It was said by Sæmmering, that it is most common in the posterior part of the urethra, in the vicinity of the bulb, sometimes in front of this, but never in the pros-

tatic portion of the canal. This last assertion has been disproved by Sir Astley Cooper and Lallemand, who have described cases in point. Mr. Phillips contends that, although strictures may be seated in any portion of the urethra, at least of any part of the spongy canal, the point of junction between the membranous and bulbous portions is most commonly affected.

Symptoms.—The symptoms of stricture are, retention of a few drops of urine in the urethra, after the whole quantity is supposed to have been discharged; so that when the penis has been returned within the dress, the shirt is slightly wetted; there is a more frequent desire to pass urine than in health; a person in health evacuates the bladder three or four times in twenty-four hours, but much more frequently when stricture is present. In the latter case, there is often an urgent desire to evacuate the bladder, but when an attempt is made, there is an inability and a degree of straining experienced for a few seconds before the act can be completed. The stream of urine is diminished in size, is spiral, crooked, forked, and sometimes escapes in the form of a thin sheath, which towards the end of the flow of urine becomes subdivided into several jets. Sometimes the urine is voided drop by drop, and it often insensibly escapes in this way, causing humidity and coldness of the scrotum. In some cases there is a slight or considerable discharge of ropy mucus, especially in aged persons, but more generally resembling gleet. When the urine is discharged, it is transparent as usual, but after it has cooled, it becomes turbid or yellow, and the mucus falls to the bottom of the vessel. This arises from inflammation of the mucous coat of the bladder; and when the disease is violent, the urine becomes quite white. When ulceration follows, the urine becomes bloody, and mixed with pus. In those cases in which suppuration takes place, the urine will be more or less loaded with pus, the patient will have severe rigors, and hectic symptoms. It is right to mention that slight shivering fits are frequently experienced in the milder forms of stricture. The most common symptoms of stricture then, are, more or less difficulty of voiding urine; a frequent, incomplete, and painful emission of it, the jet gradually becoming smaller, bifurcated, spiral, or like a thin sheath, or otherwise mis-shapen; entire retention, or incontinence of urine; retention of the semen during coition; heat and pain in the canal; blennorrhagic discharge, which is exasperated after erection or coition; and rigors more or less severe*. These symp-

* The shiverings are often so great as to be mistaken for ague. We have known a gentleman who was supposed to have laboured under intermittent fever for ten years, whose disease was stricture. He was greatly astonished on hearing our opinion.

toms will vary in different subjects, and some of them may be absent. The stricture may come on rapidly, or very gradually, during a period of three, five, or more years, without manifesting all its characteristic symptoms.

The patient notices at first that he has occasion to micturate more frequently than usual; and that he is obliged to get up three or four times during the night to pass his urine. He occupies more time in micturition, though he voids but a small quantity on each occasion. The jet becomes progressively smaller, and less strong than usual; there is sometimes a slight scalding, heat, titillation or itching, during its passage, and a feeling of weight in the perinæum, with a sensation as if there was a necessity to evacuate the bowels. According as the obstruction in the canal increases, the patient occupies more time in emptying the bladder, and requires to make stronger efforts for that purpose than formerly. If, after having accomplished this object, he makes further attempts, he procures a further evacuation. Should he not obey the call of nature, when the bladder contains urine, he experiences a dull pain in the groins, and above the pubes, which may be accompanied by considerable nausea. When the disease has advanced, the difficulty may become so considerable, and the jet so small, that the urine, instead of being ejected to some distance, falls drop by drop between the legs. In some cases, the patient may be obliged to make strong efforts, and be a minute or two before he can pass a single drop of urine, and he may occupy ten minutes before he can relieve himself. In extremely bad cases, he strains very violently, the respiration is considerably impeded, the face becomes flushed, perspiration suddenly appears upon the forehead, the whole body trembles, and the fæces are sometimes expelled at the same time with the urine. After he supposes that the bladder is evacuated, the urine comes away in drops, so that there is a degree of incontinence. This is caused in two ways by stricture. When there is much obstruction, a portion of urine remains behind the stricture, and escapes involuntarily after the straining efforts to empty the bladder have ceased; or, in bad cases, the bladder becomes very much distended, the sphincter loses its power, the stricture performs its function, but of course imperfectly, and the result will be incontinence of urine. This

He was soon after attacked with perinæal abscess, urinous infiltration of the scrotum, succeeded by gangrene, and life was saved with much difficulty. The patient is now in good health. We have known another gentleman whose shiverings misled some of the first surgeons in a northern city, and whose disease was stricture of the urethra.—*Ed.*

will be more urgent whenever the patient walks, stands, coughs, laughs, or evacuates the bowels.

The constant discharge of the urine excites irritation and inflammation in the urethra, accompanied by a mucous discharge, which may be thin, or so viscid as to plug up the urethra, and cause retention of urine. In such case the patient strains violently in endeavouring to micturate, and sometimes expels the plug; or, if this do not happen, the introduction of an instrument may dislodge it. In some instances there is a considerable quantity of common orropy mucus discharged, especially in old persons, or in chronic stricture. This is very much increased by coition, as the irritation produced during this act increases the urethritis, however slight it may be.

When stricture has rendered the urethra nearly impervious, it gives rise to great suffering and danger. The secretion of urine proceeds incessantly, the bladder becomes distended, there is a constant desire to evacuate it, accompanied by agonizing pain, extending to the kidneys, loins, abdominal and pelvic viscera, external genitals, and lower extremities.

In some instances rupture of the bladder, inflammation of the ureters, kidneys, and peritoneum, may be excited, or the urine may escape among the abdominal viscera into the cellular membrane of the perineum, scrotum, abdominal parietes, and thighs, causing inflammation, suppuration, or gangrene. Bad stricture of the urethra may induce disease of the heart, lungs, brain, or abdomen, as hernia, in consequence of the difficulty of breathing, induced by the violent and frequent efforts made to empty the bladder. I have known a gentleman who, from great straining, brought on abscess in the perinæum, and finally pulmonary consumption. He was obliged to strain for a minute or two on attempting to evacuate the bladder; and as the neck of that organ was very nearly impervious, and the power of seminal emission nearly gone, he gave up all idea of marriage, refused to submit to treatment, and became a confirmed drunkard, which speedily hastened his death.

But the most frequent diseases induced by it are those of the genito-urinary apparatus, and the vicinal organs.

When we examine the bodies of those who lose their lives by urethral obstruction, or its consequences, we generally find the following results:—Stricture in some part of the urethra, but most frequently anterior to the bulb, at the junction of this part with the corpus spongiosum. The next seat of the disease is in the membranous portion, or that part of the canal between the bulb and prostate gland; the next is in the prostate itself, according to Sir A. Cooper. All the urethra behind or posterior to the stricture, is very much en-

larged, and more or less inflamed and sometimes ulcerated, and the coats of the bladder are very much thickened, and assume a columnar appearance, on account of the repeated and powerful contractions of the muscular fibres to evacuate the organ. The ureters are generally enlarged to a considerable size; in some instances as thick as the finger or intestine, and even ten times the usual size, as they are compelled to perform in some measure the function of the bladder. The kidneys are generally diseased, the glandular part absorbed, the organ so distended with urine as, in some cases, to fill the whole abdomen.

There are various specimens of enlarged ureters in the different museums, and some good illustrations of them in Mr. Cross's work on the Formation, Constituents, and Extraction of Urinary Calculus, lately published. This writer also delineates a vast number of morbid appearances of the prostate gland, bladder, and kidneys, caused by stricture of the urethra, contraction of the neck of the bladder, disease of the prostate, calculus in the bladder, ureters, and kidneys.

The prostate gland is usually diseased, frequently enlarged, its ducts dilated, and abscesses and fistulæ are often found in it. In some cases the urethra will ulcerate behind the stricture, and the urine will become extravasated into the surrounding cellular tissue, forming urinary abscess or fistulæ, or mortification may destroy the patient, unless the perineal tumour is opened or burst. In such cases a low fever, resembling typhus, supervenes; coma and death speedily ensue. In bad cases of stricture, the general health suffers very much, the patient becomes emaciated, nervous, feeble, his spirits are greatly depressed, his intellectual powers are often impaired, his countenance is ghastly and anxious, he becomes intemperate and affected with stupor, and a premature death puts an end to his existence. Urinary abscesses occur in the perineum, and contain an extremely fetid, sloughy matter; and when they burst, the urine escapes through them. These fistulæ may exist in any part of the perineum, may extend to the scrotum, and even to the back part of the thigh*. The urine escapes through these fistulæ, and they become lined by a tissue very much resembling mucous membrane. It is a singular fact, that false passages in the urethra are also lined in the same manner, as may be seen in several specimens in the museum of the Royal College of Surgeons. In some cases the urethra is contracted or strictured for three or four inches†; in others, there is a part of the canal encircled as if surrounded

by a packthread, tape, or ribbon, or there may be a membranous band or bridle running from one side of the urethra to the other, the base of which will be broad and formed by induration of the mucous membrane, the result of repeated inflammation. Again, we may find an induration projecting laterally, superiorly, or inferiorly into the canal; and its structure may, in some cases, approach to cartilage. There may be one or several of these indurations, and the contractions are generally very irregular. We sometimes observe a stricture at a certain point of the urethra, as if a packthread were drawn tightly around the canal; but this is comparatively of rare occurrence. In general we find a projection on the inferior, superior, or lateral surface of the urethra; and sometimes two of these, so as to approach each other. Again, the stricture may be one, two, three, or more inches in length. Caruncles, or carnosities, may be detected, but these are of rare occurrence.

Lectures on Diseases of the Lungs and Heart.

By Thomas Davies, M.D. Physician to the Infirmary for Asthma and Consumption, Assistant Physician to, and Lecturer on the Theory and Practice of Medicine at the London Hospital. Svo. pp. 512. London: Longman and Co. 1835.

THE distinguished author of this work has studied the diseases of which he treats, under the great Laennec, and has given ample proofs, in the production before us, of his consummate knowledge of the nature and treatment of diseases of the lungs and heart.

It is gratifying to peruse the work of one who thoroughly understands his subject, as the reader will be instructed in every page. Dr. Davies stands among the first stethoscopists in this metropolis, and is extensively consulted by his contemporaries. He does not arrogate to himself any superior knowledge, like others that might be mentioned, nor does he pretend to more success in his practice than his contemporaries. Like all honourable and educated members of our profession, he is content with describing the important subjects which he proposes to elucidate, without pretending to a greater quantum of knowledge than the profession, either living or dead, though he is fairly entitled to the first rank of auscultators. He speaks of his predecessors and contempora-

* Stafford on Strictures. Second edition. 1829. p. 39.

† Sir C. Bell's Letters on the Urethra.

ries with candour and proper feeling, and awards every one his due.

He modestly apologizes for publishing his work when Dr. Forbes' translation of the imperishable production of the illustrious Laennec, and Dr. Hope's valuable monograph were before the profession. But he might have justly added, that he had presented the facts in both, with many others, to his readers.

Dr. Davies is, however, by no means a mere compiler; his original views are numerous and important, and he has combined them with those of preceding authors. His work is a valuable addition to the records of medicine. It is a systematic treatise which does no more admit of review than a dictionary. Suffice to state, that it contains all that is known concerning the value of Percussion and Auscultation, as applied to the investigation of the diseases of the respiratory organs and heart. It is a graphic work, which will hold a high position in our medical literature. It evinces the fullest information and experience on the part of the author. It will be a work of reference and authority. The author is entitled to great credit for the manner in which it is executed.

Practical Examinations on the Immediate Treatment of the Emergencies that occur in Surgery and Midwifery; systematically arranged. Intended to serve as an Exercise to the Student, and a brief Work of Reference for the General Practitioner, Part ii. By W. S. Oke, M.D. 8vo. pp. 163. London: Longman and Co. 1835.

THIS little work is what it professes to be, one of reference to the student and practitioner. It contains a full account of the pathology and treatment of dislocations and fractures, chiefly compiled from the works of Sir Astley Cooper and Mr. Guthrie. The author has given the whole of the opinions and practice of these eminent surgeons in a condensed form. His work will therefore be valuable to those who do not, or cannot possess the more expensive productions of the two distinguished surgeons whose names we have just mentioned. It is a concise, yet comprehensive treatise on dislocations and fractures. It ought to be in the possession

of all students and medical practitioners.

A Treatise on Pulmonary Consumption; comprehending an Inquiry into the Causes, Nature, Prevention, and Treatment of Tuberculous and Scrofulous Diseases in general. By James Clark, M.D. F.R.S. 8vo. p. 399. London: Sherwood & Co.

DR. JAMES CLARK is already honourably known to the profession as a distinguished practical physician, and a well-informed and judicious writer. The work before us is calculated to add to his reputation, and has the advantage of successfully blending the views of the best French pathologists with those of our own countrymen—an object frequently held out, but seldom attained, by English authors; for it is one thing to interlard a treatise with references or quotations sought out for the occasion, and another to imbue it with the general information derived from an extensive and well-digested course of reading.

The present work is based on the article *Tubercular Phthisis*, written by Dr. Clark for the *Cyclopædia of Practical Medicine*, several additions and alterations having been made, which may be considered as improvements on what was originally excellent.

In the introduction our author observes, that the researches of the French pathologists, however accurate and useful in their relation to the morbid anatomy of phthisis, "have tended to keep up the idea that consumption is a local disease referable to a local cause; and thus the investigation of the constitutional origin of tubercles—by far the most important part of the subject—has been neglected." The illustration of the peculiar diathesis which gives rise to tubercles, is a principal object of Dr. Clark's publication, on some parts of which we now proceed to comment very briefly.

Chap. 1. treats of *Tuberculous Cachexia*, the term by which our author has before designated the scrofulous diathesis, in his work on "The Influence of Climate." The general peculiarities of the strumous constitution are sufficiently familiar; but Dr. Clark is of opinion that a primary affection of the digestive organs, on which most of them depend, has not attracted sufficient attention.

"The dyspepsia of the tuberculous constitution has peculiar characters by which it may generally be known. These have been fully and accurately described by Dr. Todd, under the name of *Strumous Dyspepsia*; a condition of the digestive organs which is not only present in the hereditary strumous constitution, but is capable, I believe, of generating this constitution, and of leading ultimately to tuberculous cachexia. In Dr. Todd's opinion, 'it presents a more characteristic feature of this habit of body than any physiognomical portrait which has yet been drawn of it. In this respect it is more to be depended on than either the fine skin, the clear, delicate complexion, the light hair, large blue eyes, and dull sclerotica of one variety; or the foul, dull, swarthy-coloured skin, the sallow complexion and swollen countenance, the dark hair and tumid lip of the other. It betokens, indeed, little familiarity with scrofula to connect it with any particular temperament, for it belongs to all temperaments—to the sanguine as well as the phlegmatic, to the nervous as well as the melancholic, and to all their varieties and combinations. But upon whatever temperament the disordered habit which we call scrofula may engraft itself, we venture to say that this form of dyspepsia will also there be found; and, therefore, being constantly present with it, preceding and accompanying the various symptoms which issue from it, it would be contrary to all reason to refuse to it an important share in the development of this disordered habit, and in the production of the local affections which have hitherto too much engrossed the attention, to the exclusion of a proper consideration of the constitutional disease.' I have great pleasure and satisfaction in citing Dr. Todd's observations, because they are in accordance with my own, and because they cannot, in my opinion, be too strongly pressed upon the consideration of the profession; so much importance do I attach to this disordered state of the digestive organs as a source of tuberculous disease.

"I shall now notice the leading symptoms by which this affection of the digestive organs is characterized—more especially in children, in whom it is so important to attend to it. The tongue is redder than natural, especially towards the extremity and along the margins; the anterior part is thickly spotted with small red points of a still brighter colour, the central portion being more or less furred, in general according to the duration of the disorder; sometimes the tongue is covered with a dirty whitish fur, through which the red papillæ project; in which case the central part of the tongue is often dry and of a brownish colour in the morning. There is generally some thirst: the appetite is variable, more frequently craving than deficient, seldom natural; and the breath is fetid. The bowels are gene-

rally confined, though occasionally they are too loose; the evacuations are always unnatural, generally of a pale, greyish colour, of the consistence and appearance of moist clay; and they are often mixed with mucus and partially digested food. The urine is often turbid, sometimes high-coloured, and at other times too abundant and pale. The skin is generally harsh and dry, or subject to cold perspirations, particularly the hands and feet, which are habitually cold; copious partial night-sweats are common. The sleep is seldom sound—the child is restless, and talks in his sleep, or grinds his teeth.

"When this disordered state has continued for some time, the complexion loses its natural colour, and the face has a pasty, faded aspect; the child is languid, disinclined for exercise or play, and generally fretful; a train of secondary disorders also soon appears, as a consequence of the irritation of the digestive organs. The internal fauces become full and red, inflammatory sore-throats are common, and the tonsils often become permanently enlarged. The nose is generally dry, or discharges thick mucus in large quantity; and epistaxis occasionally occurs. The eye-lids are subject to chronic inflammation; and eruptions behind the ears and on the scalp, or other parts, are very frequent. Copious discharges of mucus, sometimes mixed with blood, take place from the bowels, and from the bronchial membrane; and are indeed common from all the mucous surfaces. The brain and spinal marrow frequently become the seat of secondary irritation, and hydrocephalus, epilepsy, and chorea, or paralysis may be the consequence; but the most frequent and most important of all the consequences of this disordered state of the digestive organs is tuberculous cachexia."

Chap. 2 is on *Tuberculous Disease of the Lungs, or Pulmonary Consumption properly so called*. The first section contains a good practical description of the disease, divided, according to the usage of most writers, into three stages. The second section is on *the more marked varieties of consumption*. To our author's description of these we would particularly direct the attention of the junior practitioner; they are forms of disease which continually occur in practice, but several of which will appear quite new to those who have derived their ideas of pulmonary consumption from systematic works on medicine.

Five of the less frequent forms of consumption are here noticed, viz.: Acute or Rapid Consumption, Febrile Consumption, Chronic Consumption, Latent Consumption, Infantile Consumption. We make no apology

for extracting entire the description of *febrile consumption*, which, though new to nosology under this designation, is an affection which must occasionally have presented itself to every experienced practitioner.

"Febrile Consumption."—This form differs materially in its symptoms from the more common acute varieties which have just been noticed, as well as from the usual form of the disease; even the morbid appearances discovered after death are somewhat peculiar. The degree of fever by which it is usually ushered in and attended during its whole course, is one of its most remarkable features, and the one from which I have ventured to denominate it *febrile consumption*.

"Its attack is generally sudden, occurring in a state of apparent health, after exposure to cold, or even without any very evident cause. I say apparent health, because I believe that the disease only occurs in persons of a tuberculous diathesis—the most marked cases which have come under my notice having occurred in families, several members of which had already fallen victims to the disease in its usual form.

"It commences with shivering, followed by heat of skin, quick pulse, and the other symptoms of fever, which often continue for several days with little or no indications of pulmonary disease; in some cases putting on the characters of bilious, and in others of catarrhal fever, for either of which it may be mistaken.

"Cough generally soon appears, and hurried breathing is one of the most remarkable symptoms. The cough speedily becomes more frequent, and is soon accompanied by some expectoration, which is at first colourless, afterwards assumes a yellowish or greenish hue, and is occasionally streaked with blood; but it has rarely the characters of the expectoration of the advanced stage of ordinary consumption. Pain of one or both sides frequently occurs, and occasionally there is diarrhœa. The fever, in the meanwhile, continues without abatement, and is so much out of proportion to the other symptoms of pulmonary affection, as to render the true character of the disease liable to be overlooked. In the course of from three to six or seven weeks the patient sinks.

"As the case advances, its nature generally becomes more evident; but still the symptoms are often so little marked as to render it doubtful whether the disease is not acute bronchitis or pneumonia; and when either of these affections complicates the tuberculous disease, the diagnosis becomes extremely difficult. In some cases auscultation assists us materially. The upper part of the chest often gives a dull sound on percussion, although the tuberculous matter is less frequently confined to the summit of the lungs in this than in the other forms; a circumstance which constitutes one of its patholo-

gical characters. The whole of one side of the lungs and even a large portion of both appears to be attacked in some cases almost at the same time, giving rise to a dull sound on percussion, and bronchial respiration. Under such circumstances it is difficult to distinguish the disease from pneumonia. The negative symptoms assist us: we have neither the crepitant rhonchus which precedes the dull sound and bronchial respiration, nor the characteristic sputa of pneumonia. When, on the other hand, this sudden deposition of tuberculous matter does not take place in the pulmonary tissue, but occurs in the minute terminations of the bronchi and in the air-cells to a great extent, the case resembles acute bronchitis more than pneumonia. Here again we derive assistance from the negative symptoms; the bronchial sputa are wanting, and the whole progress of the disease differs from that of bronchitis; there is also, for the most part, an extreme rapidity of breathing, which is not observed in any other pulmonary affection. But there are cases respecting the real nature of which the most attentive observer, aided by all our means of diagnosis, may be in doubt.

"The morbid appearances of this form have been well described by M. Louis and Dr. Carswell. They are of two kinds: in one class of cases they consist of that form of tubercle denominated grey granulations, deposited in great numbers in the lungs, the surrounding pulmonary tissue being infiltrated with serosity, which, as Dr. Carswell remarks, greatly augments the dyspnoea, and may prove fatal by inducing asphyxia. In other cases the pulmonary tissue is completely infiltrated with tuberculous matter, a large portion of the lungs being converted into a mass of cheese-like substance. Louis considers this form of tuberculous deposit, when it exists to a considerable extent, peculiar to acute phthisis. Tuberculous cavities are found in some instances, but they are generally of small size, are only partially evacuated, and have no lining membrane, which is commonly the case in cavities of longer duration.

"Notwithstanding the rapidity of febrile consumption, it is often attended with those morbid affections of other organs which accompany the disease in its usual form, such as ulceration of the intestines, larynx, and trachea, and the diseased states of the mucous membrane of the stomach and the liver; showing that it is true to the general character of phthisis, although differing from it in its external features.

"The diagnosis in the early stage of this variety is often attended with difficulty. The sudden attack of fever, with rapid respiration and some cough, occurring in a person of tuberculous constitution, should excite suspicion; and the continuance of the symptoms despite the remedies employed, together with the absence of those symptoms which charac-

terise the common acute diseases of the chest, will greatly assist us. Percussion and auscultation will also lend their aid in many cases.

"Febrile phthisis appears most frequently to attack young persons, although the subject of one of Louis's cases was in his forty-sixth year; it also occasionally supervenes upon the common form. In this case the breathing becomes very difficult and rapid; still the chest preserves its resonance, the respiratory sound being accompanied with a slight rhonchus. On examination after death, a large quantity of grey granulations is found diffused over a great part of the lungs, in addition to the tuberculous disease existing previously to the acute attack.

"It is proper to remark, that the disease which I have described has been considered as a form of pneumonia, the grey granulations being regarded by Andral as the result of inflammation of the air-cells: and on this view there will be equal propriety in considering the rapid tuberculous infiltration of the lungs the result of inflammation in a tuberculous subject. I do not think it of much consequence to dispute this point. I believe that inflammation in a tuberculous constitution may give rise to the deposition of tuberculous matter in place of coagulable lymph, which in healthy subjects is its natural product; and thus inflammation may be one of the immediate causes of tuberculous disease."

Under the head of *latent consumption*, we find the following remarks on what has been called *dyspeptic phthisis*.

"The complication of dyspepsia with tuberculous disease is not an infrequent cause of the latter being overlooked, the dyspeptic symptoms being more evident than the phthisical. The aspect of the patient in such cases is pale and unhealthy; he gets thinner and weaker; the food which he takes affords him neither nourishment nor strength; and yet he has no evident ailment but what is referable to the deranged state of the digestive organs. There may be no cough, no fever nor expectoration to excite fears for his safety; while at the same time tuberculous disease of the lungs is gradually extending in these organs. This is the form of the disease which has been termed *dyspeptic phthisis*; a term which I consider decidedly objectionable, if used to designate a species of phthisis differing from the tuberculous; because, however prominent may be the dyspeptic symptoms, and however obscure the tuberculous disease of the lungs, the latter is the cause of death. While I admit to the fullest extent the necessity of attending to the state of the digestive organs, I must object to the pathological view which limits the attention of the practitioner to the dyspeptic or hepatic affections, neglecting other and equally essential parts of the treatment. I do not know such a disease

as dyspeptic phthisis as constituting a particular species; but I am well acquainted with the chronic form of tuberculous consumption which is long preceded and accompanied by dyspeptic symptoms. Indeed, tuberculous consumption rarely occurs in the middle periods of life without this complication; but the deranged condition of the digestive organs is, in these cases, very often a more consequence of a long pre-existing state of venous congestion of the abdominal viscera; and which, if not corrected by more efficient measures than those generally adopted to relieve the dyspeptic symptoms, may terminate in pulmonary consumption.

"The profession is highly indebted to Dr. Philip for directing its attention to the congestive state of the hepatic system, and pointing out some of the most effectual means of obviating it; but I cannot admit that his dyspeptic phthisis differs in its nature from tuberculous consumption."

In the justice of these remarks we entirely concur.

Diabetes and diarrhæa are alluded to as affections complicating and disguising phthisis. Among diseases of this kind, *hysteria* is perhaps not unworthy of notice. As a complication of phthisis, it may occasion many anomalous symptoms, and render the diagnosis obscure; while in a few instances we have known this protean disorder to mimic so closely some of the more prominent symptoms of consumption, as pain in the chest, with dyspnoea, obstinate cough, and expectoration, even accompanied with excitement of the pulse, hectic flushes, &c.—that considerable attention has been necessary to detect the real nature of the case.

Our author's observations on infantile consumption are worthy of an attentive perusal. Phthisis was formerly little heard of as a disease of childhood; the recent researches of morbid anatomists, however, have demonstrated that it is by no means unfrequent, even in infancy.

Consumption at an early period of life differs somewhat, both in its symptoms and the seat of the tubercular deposition, from the same disease in adults.

"The cough is very often of a character different from that which accompanies consumption in persons of mature age; it frequently occurs in paroxysms resembling those of whooping-cough, and is rarely attended with expectoration till a late period of the disease, and as the matter is frequently swallowed, we are deprived of the light which the cha-

acters of the expectoration might throw upon the nature of the disease. Hemoptysis is a rare occurrence; at least, I do not recollect to have met with any case in which it was present. The hectic fever is likewise less perfectly formed, and the perspirations are generally less abundant than in the adult.

"The disease, however, if we attend to the other symptoms, is not usually difficult of detection:—the tuberculous aspect of the child, the rapid pulse and breathing, the frequent cough, and the gradually increasing emaciation, commonly afford sufficient evidence of its nature. Consumption in children is often preceded or accompanied by considerable derangement of the digestive organs; the abdomen is tumid, the bowels are irregular, at one time constipated, and affected by diarrhoea at another; the evacuations in either case are generally of a pale, unnatural colour. This deranged state of the functions of the abdominal viscera has led to the belief that the mesenteric glands were the chief seat of tuberculous disease; whereas, in reality, the bronchial glands and lungs are most commonly affected. It is true that the mesenteric glands become tuberculous more frequently in infancy and childhood than at a later period of life, but by no means so generally, nor to such an extent, as is supposed.

"The disease often commences in the bronchial glands, occasionally proving fatal without affecting the lungs or any other organ; and hence it has been denominated bronchial phthisis (*phthisis bronchique*); and, if the term phthisis be confined to the disease arising from tubercles, the name is unexceptionable. This form is almost peculiar to childhood; at least it is much more frequent at this period of life, and it is at this age only that tuberculous disease is confined to the bronchial glands."

According to the observations of M. Andral, the bronchial membrane in the vicinity of the diseased glands is generally inflamed, just as the intestinal mucous membrane is frequently found to be when the mesenteric glands are tuberculous; this, however, is not invariably the case, as in some instances the same eminent pathologist found the bronchial glands tuberculous where no symptoms of catarrh had existed during life, and no traces of inflammation were discoverable after death.

"The symptoms which indicate the presence of tuberculous disease in the bronchial glands are generally obscure for some time; hence they may be tuberculous without being detected, as it is not until they acquire a considerable size, and irritate or compress the bronchi mechanically, that the local symptoms become evident. The child coughs, is short-breathed, very liable to

catarrh, and occasionally points to the upper part of the chest as the seat of uneasiness. But the same symptoms may be produced by common catarrh or pulmonary tubercles. When the diseased state of these glands is further advanced, the nature of the case is more easily detected. If cough, hectic fever, and emaciation occur in a child, and a careful examination discovers tuberculous disease neither in the lungs nor in the mesenteric glands, we may feel tolerably certain of its existence in the bronchial glands."

Although the tuberculous disease may prove fatal while confined to the bronchial glands, it seldom remains limited to these for any length of time, but soon involves the substance of the lungs, thus occasioning a complication in the symptoms.

"It is not quite a matter of indifference whether the seat of the tuberculous disease be the bronchial glands or the lungs. In the former situation the progress of the disease is slower, continuing in some cases for years, during which the little patient may enjoy pretty good health; the disease, being seated in organs much less essential to life than the lungs, interferes less with the general functions of health, and time is afforded for the correction of the constitutional disorder.

"The termination is various. That the tuberculous matter deposited in the bronchial glands may be removed by absorption, as occurs in the lymphatic glands of the neck, we have every reason to believe; but this is, no doubt, the less frequent termination. Another mode of cure is that by which the softened tuberculous gland empties itself into the bronchial tube with which it is in contact, in consequence of ulcerative absorption of the walls of the tube, as is shewn in Dr. Carswell's illustrations. The matter having passed into the bronchial tube, the cavity in which it was contained gradually contracts till it is obliterated; and the cure, as far as this gland is concerned, is complete. The less frequent cure is that in which a portion of the gland, or rather of the tuberculous matter, remains in a cretaceous state.

"The prognosis of this form of consumption must always be doubtful, inasmuch as it depends on circumstances which we are generally unable to ascertain, namely, the extent to which the bronchial glands are diseased, and whether tuberculous matter is at the same time deposited in the lungs; the degree of tuberculous cachexia under which the child labours, and the character of the constitution generally, will also materially influence our opinion respecting the ultimate result of the case. The prognosis, however, will be more favourable than when the disease exists in the lungs."

(To be continued),

ENTRY OF A JUNIOR MEDICAL PRACTITIONER INTO THE WORLD.

A YOUNG physician or surgeon who has passed some of the best years of his life in the lecture rooms, hospitals, and libraries, expects, on receiving his degree or diploma, to acquire fame and fortune on commencing his professional career. He is well acquainted with the principles of his art, and closely follows them. He employs all that he has heard and read on the investigation of the nature and treatment of disease. He is a scrupulous observer of the rules of art, and fears to break them in their application; he examines with great care, and gives his opinion with diffidence or fear. He is cautious and timid in the use of remedies. The better informed he is, the less presumptuous or rash he will be in practice. He is in general diffident in himself, hesitates or is too anxious about his patient, and is for some years before he acquires a confident assurance, which is the result of experience. He generally supposes that he has mistaken the disease, and has not done enough for its removal. This is the ordinary feeling of the best informed medical practitioners in the commencement of their career; but experience will in time remove it. The complication or intensity of disease may be such that no remedial means can preserve life. The contrast between well-informed and ignorant practitioners is very remarkable.

It has been long remarked that the most uninformed in every science and art are, in general, the most confident and self-sufficient. This is also the case with pretenders to medical knowledge. No case is too dangerous for them; they can cure all diseases, though they kill a vast number of patients. They attribute all their failures to the intensity of disease, and not to their own ignorance. As they have had no preliminary or medical education, which is so necessary to prepare the mind for the investigation and estimation of morbid phenomena, they treat diseases by names, and not according to their real nature. Men of unlettered ignorance usually pride themselves on imagined practical experience, or on what Cullen aptly termed "false facts," and blindly pursue the same erroneous system without a particle of sound judgment. In fact, nothing appears beyond their ability, or too difficult for them to attempt. They can cure all diseases—a power only possessed by empirics; they ascribe their success, in cases in which nature effected a cure, to their active interference, but they never suppose that their failures are in any degree the result of their incapacity. They do not know that experience, without a proper scientific education, is useless.

It cannot be denied, that unless a medical practitioner knows the anatomy and physiology of the human body, or, in other

words, the phenomena of the animal economy, his observation and experience are based on ignorance, and must be erroneous. Such is the advantage of experience, unaccompanied by proper medical information. On the other hand, the well educated junior or senior practitioner, who has had the most extensive experience and information, is always diffident in his own powers, and doubtful of the result of the disease. He never professes to cure every patient.

But I must return to the career of the young physician or surgeon. On receiving his diploma, he is most anxious for fame, and thinks the world ought to be instantaneously aware of his qualification to practise. He, however, speedily discovers, that the world esteems him as a student, and that he is not a more important individual than he was the day or month before he received his qualification. He speedily discovers that patients will not consult him. Some suppose him inexperienced, and too youthful; others have their own medical advisers; and all will prefer practitioners of standing to our young *Æsculapian*. He now thinks that his youth is a great or invincible obstacle to his success, and he sighs for the time in which the public will reward him for all the labour and expense he has incurred in the study of his art. Nevertheless, every other member of the profession had the same difficulties to contend with, and only surmounted them by time, attention, skill, and unexceptionable morality. He does not imagine that a physician, extensively engaged in practice, has any cause to complain. He does not know that such an individual is deprived of all pleasure, recreation, or amusement, and regrets the period of his studies, when he enjoyed liberty. Thus, man is never content with his condition.

The first success or failure of a physician depends on the opinion entertained by the public of his talent. How embarrassing and difficult is the debut of a physician in the world. How careful he must be in gaining the confidence of his first patients, in investigating the symptoms of their diseases, and in employing remedies. He must recollect that others of his faculty have been consulted on former occasions, and that their manners and conduct will be compared with his own. When the disease is dangerous, and he effects a cure, he will greatly benefit his reputation. His religion and zeal compel him to attend the poor and miserable, as well as the comfortable and affluent; and he may gain reputation by both. He will often succeed after his seniors have failed; because they in general belong to the old school, and he to the new. He should not expose their errors, unless glaring, and dangerous to the life of the patient. He is always ready to afford relief to suffering humanity, with or without remuneration. In the same manner, a surgeon should never refuse to perform a doubtful operation when

it is required. The patient ought to have every chance. Either physician or surgeon can explain to the relations the danger of any case.

The essential requisites of a physician are, in addition to the possession of all the virtues, knowledge of the world, and polished manners, an earnest desire for fame, a great love of study, a good knowledge of charlatanism, and what is vulgarly termed humbug, a good share of small talk, and an audacity which nothing can disconcert. The critical reader will inquire, why a medical practitioner should be acquainted with charlatanism and humbug? The answer is, because it is the nature of mankind to esteem quackery, as it professes to effect cures of incurable diseases. All classes of society encourage and patronise empiricism; but an immense crowd of fools constitute the public. In all countries the most absurd quackeries have been patronized, but this is easily explained, when we dispassionately observe the varied degrees of intelligence, and the love of life and of the marvellous which influences all ranks of society.

It must be confessed, though a stain on the dignity of the medical profession, but equally remarkable in every class of society, that some *Æsculapians* have acquired success, fame, and opulence, by fostering the follies and prejudices of the world; and acting as arrant humbugs.

Such men are, however, despised by their brethren, who, in general, are actuated by the love of humanity and reputation. The former are despised by the honourable cultivators of medicine, notwithstanding their titles, station, and influence.

The medical profession has great reason to complain of the follies and injustice of the public. The mass of fools forming the public, with few exceptions, will ascribe professional success to chance or to nature, and if the patient dies, some will not hesitate to declare that the doctor killed him.

They will unhesitatingly proclaim the incompetency of the medical practitioner, unmindful of the well-known and unfortunate truism, that many diseases and many constitutions are utterly incurable.

M. Lorry, a celebrated member of the profession, has happily exposed the folly of the public in this respect. He says—"A physician fond of study, has spent many years in the schools, hospitals, and anatomical rooms; he has passed the best years of his life in the infected air of hospitals, the pallor of his countenance, and the meagreness of his figure, attest the multiplicity of his vigils, and what remuneration compensates for these labours?"

Here the ignorant man of the world declaims against the stability of one of the noblest of human sciences, and unblushingly confounds medicine and empiricism. Thus there are many, whose lives have been

saved by medical practitioners, forget it, and even denounce the medical faculty.

If the public do not derive the usual advantages from medical practitioners, they should blame themselves for encouraging illiterate pretenders to medical knowledge, nominal doctors, and empirics. Such impostors are very numerous in all countries; and if the public do not take the trouble of distinguishing the learned from the ignorant, the fault is their own. If the nobility and gentry prefer the St. John Longs and such basket makers, the Hahnemanns, and other empirics, the woodmen of Molière to well educated and eminent medical practitioners, they must not decry the benefits of the healing art, and depreciate the Coopers, Bells, Dupuytren, &c. &c.

In general, young medical practitioners are most attentive to their patients, and render them the greatest services. So do all duly educated members of the medical profession, who are influenced by the code of ethics laid down for their guidance. There are some, however, among the eminent in all countries who are a disgrace to the profession. They take advantage of public credulity, which in all ages has rendered the worthy part of mankind dupes to the artifices of the knavish; who, unrestrained by principle, are ever eager to profit by the unsuspicious disposition of generous minds. Among the various kinds of imposture practised on society, quackery has always been the most successful, in consequence of the extreme respect paid to the professors of the healing art. These have now and then availed themselves in acquiring reputation on the foibles of the public.

Reputation of a Physician.—When the desire of reputation is inspired by the love of fame, it is allowable, because it tends to the good of society. It has been often observed that those physicians who have not a laudable ambition to rise to eminence by their talents and honourable conduct, seldom or ever become renowned. They remain every-day characters, and never obtain the highest places in the profession. When a thirst for gold is the only object of professional reputation, it leads to meanness and disreputable behaviour. We see empirics, illiterate and professional, amassing great wealth at the expense of every virtue which adorns the true medical character.

The public is the cause of this, as it awards reputation by caprice, and this is the reason that charlatans share, in common with educated physicians, reputation and renown. They announce with unblushing effrontery their marvellous powers, and all ranks of society, both high and low, are ready to believe them. Kings, nobles, and commons, patronize the empiric, no matter how preposterous his pretensions. Let him be an animal magnetizer, a homœopathist, an extractor of all diseases with a stimulating,

liniment or metallic tractors, it is all the same. Witness the patrons of a Long and a Hahnemann, of a Graham and his celestial beds, from which a noble race of offspring was to follow; witness a scion of nobility attesting, three years since, that he saw a quack extract quicksilver from a lady's brain. Look to the noble patrons of Hahnemann, who believe the most salutiferous doctrine, that the millionth part of a grain of magnesia or of sugar could not only cure a city, but an empire, however extensive.

What difficulties, on the contrary, has the modest man to surmount before he can obtain the smiles of public favour.

There is, however, in medicine, different kinds of reputation which lead to fame and fortune. One gives himself up to scientific pursuits, another distinguishes himself by writing or teaching, a third is renowned as an excellent physician, a fourth as an operative surgeon, or obstetrician.

It rarely happens that one individual possesses these different titles to celebrity. The healing art is too long and extensive for the greatest genius to comprehend it in all its parts. One is super or in medicine, another in surgery, and another in obstetrics, chemistry, botany, &c.

When a physician acquires reputation by merit, he should never attempt to increase it by resorting to the artifices of charlatanism, which invariably lowers him in the estimation of his brethren, and, through them, of the public. He should avoid all species of puffing, whether having nurses or relations to trumpet his abilities, or superficial works to circulate gratuitously among his connexions and their friends. If his fame be founded on talent and merit, it rapidly increases without these artificial helps—it enlarges as it progresses—*Vires acquirit eundo*.

If the cacoethes scribendi should seize one, let him write something rare, new, or nothing: *scribe rara aut nova, vel nihil*. The style and composition ought to be correct and elegant. Citations may be numerous and acknowledged, though some writers too often give the whole of other men's works and opinions as their own. These are generally detected and exposed by reviewers and critics. It is no excuse to the reader, that a work is written or printed in a hurry, and full of blemishes; the public would have waited for it with patience, and seldom care if it had never been published. An author should deliver his opinions with modesty, and expose what is true, dubious, or erroneous. He must rarely condemn others, or censure the living or dead, with undue severity. He must praise sparingly, and vituperate more sparingly. There are some writers and critics who praise no one, and vituperate every one. They find fault with every thing—style, composition, opinions, arguments, observations, and conclusions.

They hold, that every thing is to be found in the works of the ancients, and that there is nothing new under the sun. These critics raise a host of enemies against them, and seldom have any friends. They should adopt the ethical axiom:—"It is not right always to praise or dispraise"—*Nec laudare semper, nec semper vituperare decet*. *Lauda parce, vitupera parcius*. *Lauda recentes, lauda veteres, vel utrosque carpe, si licet*. *Stet sua cinque reverentia, suis honos*. *Non vivent auctores enormiter laudes, ut vicissim lauderis*. *Stet verbis, stet titulis stet sua encomiis mensura*. *Unico libello scriptores omnes, omnes amicos non alliga*. *Nec ænulorum, nec mortuorum laudes dissimules, nec excedas*.

When criticism is unjustly severe, it often becomes pointless, and only serves the circulation of a work.

There is no work free from some objection, and there is a vast number of modern publications deserving of severe criticism. Thus one man writes a pamphlet or book for the express purpose of making himself known by advertisements in the public journals; another does not state a fact that was not well known for centuries before he was born; another gets himself puffed in a sly paragraph of some newspaper; and in these, and a thousand other ways, do medical practitioners attempt to captivate the public. These schemes, *ad captandum vulgus*, are derogatory to the dignity of medicine, though they are now unblushingly laid by some of our highest physicians and surgeons. We daily observe their advertisements by the side of those of empirics, and their paragraphic puffs are most abundant.

Besides these modes of gaining fame, we find physicians and surgeons recommending apothecaries, and *vice versâ*. The female portion of their own and other families become puffers of their skill, and often succeed in increasing their fame. A lady of title has been known to make the reputation and fortune of her medical attendant.

People of fashion are led by notoriety and imitation of each other, and thus the physicians to royalty are indispensable to the nobility. No other will do.

In other instances, a reputation and a name are made by many petty artifices—by gossiping, a talent for flattery, the influence of medical and other patrons, and, lastly, by religious partisanship. These means will often raise a medical man in public estimation, though he does not possess a ray of talent; while the man of genius, of erudition, and of practical knowledge may, without them, remain in "illustrious obscurity" all his life. He sees numbers of his inferiors who, by their address, policy, and worldly wisdom, rapidly pass him by, and leave him in the shade.

Nevertheless, what a galaxy of men of genius and knowledge have risen to emi-

nence and fame. It is unnecessary to multiply examples; but be it observed, that no physician arose to greater eminence, since Hippocrates, than Boerhaave. A letter was addressed to him from China with this superscription—"To the Great Boerhaave, in Europe." The letter reached him,

ANATOMY ALIKE INDISPENSABLE TO PHYSICIANS AND SURGEONS.

ANATOMY is generally admitted to be the basis of scientific medicine, but its particular study is usually considered as more indispensable to the *surgeon* than to the *physician*. This, we think, is a great mistake; for, in the first place, we cannot perceive any valid distinction between physic and surgery, and consequently we regard what is essential to the one as equally essential to the other; and secondly, admitting the arbitrary distinction which at present obtains in the profession, we maintain, that an extended knowledge of anatomy, so far from being of less consequence to the physician than the surgeon, is of infinitely more.

It is quite erroneous to suppose that the mere operator need be a profound anatomist; the knowledge of this subject which he requires is in effect extremely limited, though it must be perfectly accurate as far as it goes. He must be well acquainted with the relation of the principal blood-vessels and nerves, to the surrounding objects—the position of the viscera, and the structure of the joints; but what is there in all this which any man of ordinary capacity may not learn in the course of twelve months' diligent attendance in the dissecting room?

Of what use to the mere operator is the minute anatomy of any organ in the body? What is he profited by the researches of Tiedemann on the brain, or

those of Kiernan on the liver? Of what use to him is general or physiological anatomy? All these things are foreign to his purpose; it is the mechanical relations of a certain number of parts, not the vital relations of the entire organism, with which it is necessary that he should be conversant.

But it is far otherwise with the physician. In comparing the various results of the same morbid action in different tissues, how important to him is the study of general anatomy? in tracing the sympathy of distant organs with those on which morbid impressions are immediately made—an inquiry into which it is probable that the greater part of the theory of medicine will one day be resolved—how essential is a minute acquaintance with the origin, distributions, and connexions of the nerves? in exploring the morbid anatomy of fatal cases, how indispensable is a knowledge of every peculiarity, however minute, of texture, colour, and consistence, in every part of every tissue in the body? what ludicrous blunders are continually committed through ignorance of such particulars, when "highly diseased conditions" and "very remarkable appearances" are libellously recorded against parts that are perfectly healthy, if the wise men did but know it!

The popular error prevalent in England, that a small knowledge of anatomy is sufficient for a physician, has arisen from the actual deficiency of those who have been looked up to as the heads of the profession of physic—the fellows of the London College of Physicians—who are not required to give any proof of having ever been engaged in the prosecution of practical anatomy—many of whom probably never dissected a subject in their lives—and who, taken as a body, are perhaps, without any exception, the worst anatomists of all medical practitioners on the face of the civilized earth. But we would hope, and are rather inclined to believe, that

some of the junior fellows have become fully sensible of the miserable deficiency of their order; are convinced that Greek, though exceedingly imposing, will not teach men to reason upon or to treat the diseases of the human body, and that the most unlettered apothecary who understands the structure and functions of the animal machine, is more adequate to the treatment of a fever than Porson himself. We are quite sure that none of our habitual readers will misconstrue these remarks into anything like a depreciation of classical and literary attainments: we have again and again expressed our opinion that medicine can never flourish long when disjoined from literature; but we must always insist on essentials before accessories—for example, *grace* is a highly desirable qualification in an equestrian, but the first and most indispensable qualification is, that he shall know how to keep his seat; the clumsiest persistence in the saddle is preferable to the most elegant projection over his horse's head; and, in like manner, the practitioner who questions his patient in bad English, but cures him of his disease, is much to be preferred to the most erudite *fellow*, who should kill him, or let him die, and then sing his elegy in Greek strains worthy of Tyrtaeus himself.

—o—

BIRTH EXTRAORDINARY.

ON Saturday, the 25th inst., in Green Lizard Street, an hospital physician was delivered of sundry cases. The only drawback to the joy which so unusual an event is calculated to produce—for time out of mind sterility has been the cleaving curse of the brains of the gentry in question—is the fact that the offspring is scanty, deformed, has no good and prominent features, and appears, indeed, to be mere wind and skin. This, however, cannot be wondered at, when we consider the pains of the head with which such parents always generate, and the vast difficulty they have ever had in bringing forth,

in the few instances on record, in which they have been tempted into the sin of propagating an idea at all.

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

(Continued from p. 329, Vol. VII.)

Evolution of certain Gases.—We could not give a complete account of the changes which occur in the different organs after inhumation, if we omitted to notice the evolution of certain gases which occasionally takes places in most of the tissues.

The stomach, intestines, pleura, pericardium, right cavities of the heart, *venæ cavæ*, and other parts of the venous system, the uterus, the cavity of the peritoneum, and the areolæ of the cellular tissue, may be distended with gases, which result from the decomposition of the fluids: this is observed particularly after speedy and violent death, preceded by acute pain and severe struggles; under such circumstances the body sometimes becomes so emphysematous as to float on water.

To the evolution of gas within the veins is to be attributed a phenomenon apparently very extraordinary, and from which the ancients supposed that a *legal* conclusion might be drawn—we mean the oozing or even spouting of blood from wounds. Is it surprising that the blood contained in the veins should escape from the open extremities of the vessels in a wound when it is propelled by gases evolved within the venous system? After having explained succinctly the phenomena which different organs present during putrefaction, it may not be unprofitable to cast a glance over the principal changes undergone by the head, chest, abdomen, pelvis, and limbs, and even by the grave clothes and the coffin.

Head.—While the head still remains attached to the vertebral column, and preserves all its connexions, the eye-lids are attenuated and so much sunk, that at first sight the orbital cavities appear to be only half filled; the globes of the eyes very soon collapse, and the nose also shrinks; sometimes, however, only at the sides. Soon after, the hair falls off; the eye-lids, soft parts of the nose, and the lips, which are already much shrivelled, disappear; a portion of the skin of the cranium is also destroyed, and the bare bones are covered with a thin layer of a bistre-coloured, fatty matter. At the back part of the head there is a sero-sanguineous infiltration under the skin, and between the periosteum and the bone, arising from the supine position of the body—consequently the soft parts are here easily detached, although the integuments

still preserve a pretty firm consistence; In the midst of all this destruction the ears and cheeks are in moderately good preservation. Here and there, on the cranium and face, we find a moist downy mould, of a green or whitish colour. Later than this, between the third and fourth month (judging at least from the examinations made at the Bicêtre), none of the soft parts of the face remain; there are only some membranous vestiges, especially about the jaws: but the inferior maxillary bone still retains its connexion with the temporal, and the head with the vertebral column—a small degree of force, however, is sufficient to disunite them. At a still more advanced period, the jaws, widely separated, expose to view the basilar process of the occipital bone; they are still united by some remains of the soft parts, and the head preserves a very feeble attachment to the trunk. Finally, the bones of the head are completely disarticulated and denuded, and those of the cranium are covered with a magma composed of earth, and hair, which, being removed, discovers their bistre-colour, shaded here and there with large patches of deep brown.

Thorax.—For the three first months the thorax rarely undergoes any change in its form or in the relative position of the parts which compose it. The cavities of the pleuræ may contain a larger or smaller quantity of fluid, but such effusion is not the result of putrefaction: the shrivelling of the thoracic viscera, and especially the lungs, is not yet so great as to produce any remarkable vacuity of the thorax. Some time after this the sternum is much depressed, and appears to be almost in contact with the spine; it is easily raised with the hand; some of the ribs begin to separate from their cartilages; the intercostal spaces at certain points are filled up with nothing but a grayish membrane; the interior of the thorax, when cut into, appears empty and lined with a membrane resembling in colour and consistence gray paper that has been soaked, nor is it evident of the remains of what parts this membrane is composed. Later than this the ribs are almost entirely denuded, and scarcely retain their attachment to the sternum, which has fallen in, is of a brown colour, and often covered with mould; almost all the sternal cartilages are separated from the sternum and ribs; those which remain are black, pierced with holes, flexible, and easily removed; they are broken without much difficulty, and their fracture is accompanied with a slight sound; patches of mould, white or variously coloured, are scattered over the internal surface of the thorax, and some of the intercostal spaces are void by the destruction of the soft parts. At a more advanced period the sternum and cartilages of the ribs have separated, their remains are scattered in the thorax and abdomen, and a

large gap is thus occasioned in the anterior part of the former cavity. Still later than this the shape of the thorax is quite destroyed, the sternum has separated into two pieces and fallen into the cavity; the ribs are almost all detached and lie upon one another on each side of the body; they are covered with a black substance resembling a moist vegetable extract, and which is formed of the remains of the soft parts; the ribs are not more frangible than in their fresh state, but their internal substance is very dry and porous; only a very few of them retain a portion of their cartilages, which are very flexible, of an olive gray colour, and covered with a brownish coating, which appears worm-eaten here and there, and presents a very porous texture when cut into; the internal substance of the cartilage is destroyed.

Abdomen.—For a long time the abdomen does not exhibit any remarkable alteration, except that its external surface becomes green, yellow variegated with green, or of an ochre colour. From the third to the fourth month, according to our observations, it collapses, and its parietes approximate to the spine; some time after its parietes are reduced to a membranous layer, which is sometimes humid, but more frequently dry, thin, brown, mouldy, and covered with earth, easily lacerable, and closely applied to the vertebral column, and even to the pelvis; when it is raised a considerable cavity is observed on each side of the spine and in the pelvis. When the parietes are in a humid state they are composed of layers of a soapy appearance and yellowish-white colour, which are usually separated from each other by an immense number of worms. Some weeks after the abdominal parietes are so glued to the spine that they cannot be easily detached, except at the sides, where they consist of a foliated layer of a blackish red colour internally, and sometimes encrusted externally with adipocere. From the attachment of the sub-umbilical parietes to the spine, a distinct cavity is formed, extending from the xiphoid cartilage to a little below the navel. Sometimes the membranous layer, which is attached to the spine, instead of presenting a smooth surface, is full of elevations and depressions. At a later period the parietes of the abdomen are reduced to some tegumentary remains, which are of a bistre, olive, or blackish colour, and often perforated in many places; they still adhere to the lower ribs, to the pubis, and to the posterior part of the iliac cristæ: these remains appear to be formed by the peritoneum, and perhaps some portions of the straight and oblique muscles, much desiccated and altered from their original texture. Finally all is destroyed, and we find nothing but a black humid matter, like the grease of a wheel, adhering to, and tinging, the bones on each side of the spine, and forming, in some places, masses half an

inch thick, which are evidently the remains of the soft parts.

The state of preservation of the abdominal viscera depends principally on the degree of integrity of the abdominal parietes; it may therefore not be uninteresting to throw a rapid glance over the comparative periods at which the latter are destroyed. With respect to the decomposition of these, as of other parts, we find an immense difference depending on causes which are often difficult to determine. Thus, we have found no traces of the abdominal parietes in one subject nine months and eighteen days after inhumation, and in another thirteen months and sixteen days after; while, on the other hand, a portion was still remaining in a body that had been buried seventeen months and six days; and, what is much more extraordinary, another body which had been interred for twenty three months and five days presented the anterior wall of the abdomen nearly entire, in the form of a membrane appearing as if tanned, with the umbilical depression visible in its centre, and with layers of a bistre or blackish colour like moistened tobacco leaves adhering to it; these layers were united to each other by soft filaments like tinder, which were easily torn. All these subjects had, nevertheless, been deposited in coffins of the same wood, and of the same thickness, each surrounded by a cere-cloth, and had been laid side by side in the cemetery of the Bicêtre. We may add to these instances, that of a subject which had been buried two years and nine days, in which no vestiges of the abdominal parietes were visible, although the body had been contained in an exceedingly thick coffin, and enveloped in a linen cloth.

(To be continued).

Hospital Reports.

MIDDLESEX HOSPITAL.

Fistula in Perineo, after Lithotomy, of six years standing, successfully treated.

A REPORT of the above case, and of the operation which Mr. Mayo performed for the relief of the patient, will be met with in the number of our journal for April 11th, at page 350, of the last volume. We are happy to say that the operation and means subsequently adopted have been so far successful, that the boy is now nearly cured of the fistula, through which no urine has escaped during the last fortnight, and of which only a very small external opening remains.

During the last two months the boy has had pressure applied to the opening in the perineum, by means of a small, oval, ivory pessary, supported on a steel spring, and connected with a steel truss passing round the loins.

In order to obtain a perfect closure of the opening in the perineum, Mr. Mayo has lately twice touched it with the actual cautery, in the form of a silver probe properly heated, under which treatment there is every appearance of any remaining vestige of the lesion speedily disappearing. At the present time, upon introducing the probe into the opening, it does not appear to pass into the urethra, or rather neck of the bladder, the opening into which is doubtless closed. The case is a highly interesting one, and its successful result cannot fail in encouraging surgeons never to despair in their attempts to remedy fistula in perineo, even when connected, as this was, with the bladder; and when, as was likewise the case in this instance, they have been of long duration, and have baffled the exertions of other practitioners.

—o—

WESTMINSTER HOSPITAL.

Erysipelas Gangrænosum—Death.

DANIEL GRIFFIN, a labourer at the gas-works, aged 50, was admitted into Henry Hoare ward, July 15th, under the care of Mr. White. It appears that, having been suffering from an arthritic affection of the left ankle joint, attended with a good deal of swelling, he had been attending as an out-patient at the hospital, in the physician's department. Amongst other remedies prescribed for his relief, was cupping over the joint, and this was performed on Saturday, the 11th ult. He states, that on the application of the scarificator, he felt a very severe pain, "just as if the instrument had gone to the bone." The next day (Sunday), the swelling in the joint had considerably increased, and has spread a little up the leg, but does not appear to have attracted much of his attention. The redness, however, and other inflammatory symptoms, continuing to increase, he was transferred to the surgeon's care, and taken into the hospital. Upon his admission, the attack appears to have been regarded as principally rheumatic; and the attendant superficial inflammation, as merely a little erythema, so frequently a concomitant of arthritic inflammation. The following remedies were therefore ordered:

Rx. Ext. colchici acetat. gr. vj;

Pilul. hydrarg. 3ss.

M. ft. Pilul. vj. Capiat, j; ter quotidie.

Habebat lotio. alcoholic. Evapor. assidue applicandam.

17th. The pills have acted very freely on the bowels, indeed to an undesirable extent. The local affection has now put on a very unfavourable aspect, the tumefaction of the leg and foot has much increased, and an erratic blush of inflammation has spread up to the knee, and, on the under surface of the limb, has travelled three or four inches higher than that joint, the under sur-

face of which is very tender. The tumefied part of the limb, near the ankle and half way up the leg, is about double the healthy circumference: it is glabrous, and pits slightly on pressure. A considerable portion of the skin over the dorsum of the foot, and outside of the leg, is of an opaque white colour, almost like parchment, and appears to have lost its vitality; and there are several livid spots on the leg, which is more or less of a lurid red colour generally. Pulse 120, feeble; tongue red, with the centre furred; he talks rapidly, and in a somewhat incoherent manner; the nurse states, that he was somewhat delirious during the night.

R. Quinina sulph., gr. xx;

Decocti cinchona, ℥ viij.

Ft. Mistura. Capiat cochl. ij ter quotidie.

Repet. lotio. calid. app.

18th. Has passed a delirious night, could scarcely be kept in bed; and is almost constantly singing. Looks worse this morning; his countenance is sunken and anxious; eyes as if depressed in the orbits; the left eye is red and suffused, from turgescence of the vessels of the conjunctiva. Tongue is more deeply furred than yesterday, and there is a collection of dark sordes about the teeth and lips; pulse 144, very feeble and small. The hands and upper extremities communicate a cold clammy sensation to the touch. The leg appears much worse; a livid colour now generally predominates; the extent of surface of the dead white skin has increased. The erysipelatous inflammation does not appear to have spread much up the thigh. Mr. Soden made a few punctures with the lancet in the part where redness prevailed, and thus obtained a little blood. Warm fomentations are now kept constantly applied, and he is ordered to have four ounces of brandy in the twenty-four hours, and the following mixture:—

R. Ammon. carbon., 3j;

Liq. ammon. acetat. ℥ iss;

Mist. camphoræ, ℥ vj. M.

Ft. Mist. Capiat cochl. iij 4tis horis.

19th. Passed another delirious night; the leg gradually became worse, and the gangrenous character more apparent. The erysipelas has spread up the thigh since yesterday. He has the application of fomentations continued to the leg, and flour is dusted over the thigh. The quantity of brandy has been increased from four ounces to eight in the twenty-four hours.

Repet. mist. ut ult.

20th. Had another very delirious night. He gradually became worse, and died this morning at 10 o'clock.

No autopsy could be procured.

UNIVERSAL CODE OF GENERATION.

PART II.—GENERATION OF ANIMALS.

WHAT a vast, sublime, and at the same time delightful field, is the study of the generative functions in this class of living beings, at the head of which stands the human species! What curious and varied phenomena, all tending to the same result! What an incalculable profusion of different reproductive processes nature employs for the propagation of the numerous species which she calls to the banquet of life! And, nevertheless, what unity and what analogy of propagative actions among all the individuals of the same class, from the bramble heath on which we tread to that proud being who is so eminently qualified to be prince of animals, and king of the universe.

Though the study of the generation of animals presents to the mind of the observer a host of subjects capable of vividly exciting the curiosity, it still furnishes a host of gifts of the deepest interest, whether we consider the advantages of the beings under our empire, whether to serve our comprehension and explication of the numerous phenomena of human generation, on the mechanism of which nature would appear at first view to have thrown an impenetrable veil.

A complete history of the generation of animals, and especially of the infinity of modifications in this mysterious process of perpetuating each species, would be an immense undertaking, to which the entire life of one man would be insufficient, and which is beyond the comprehension of his natural faculties. What an infinite number of organizations and different species among the millions of living beings which the earth receives on its surface, which fly in the air, and which swim in the unfathomable ocean! What an immense number of others whose organization, and consequently the mode of their reproduction, escape the eye, even assisted by the most powerful microscopes.

How numerous are the springs, says Buffon, the powers, the machines, and movements included in that small portion of matter which composes the body of an animal! What relations, harmony, and correspondence between the parts! How many combinations, arrangements, causes, effects, and principles, which concur to the same effect, and which we only know by the results, so difficult to be understood; and they have not ceased to be marvellous, but on account of our not reflecting upon them. Nevertheless, how admirable does this work appear to us; it is not in the individual that the great wonder exists, it is in the succession, renovation, and duration of the species, that nature appears altogether inconceivable. The number of the species of animals is much greater than of plants, which amounts, it is said, to 40,000. There is, perhaps, a greater number of in-

sects, most of which escape our observation, than there is of plants visible on the surface of the earth!

It is, therefore, beyond our powers to enter into all the details which so vast a subject comprehends, and we must necessarily confine ourselves in this work to the general notions, which are the most curious and important, on the procreation of animals. We shall, nevertheless, enter into some details concerning a certain number of species; but they must be confined to the most remarkable phenomena, and the most interesting to be known for the design and object of this work.

I shall follow, in the exposition of facts relative to generation, the classification which is most generally known and adopted in these times—that of zoophytes, insects, crustacea, worms, mollusca, fishes, reptiles, and mammifera, at the summit of which stands the human species.

SECTION I.—ZOOPLYTES.—These are a species of animals where organization, sensibility, and contractibility are very little developed, so that they have been considered as occupying a middle place between the vegetable and animal kingdom. Such are the microscopic infusoria, which are sometimes seen in millions in a drop of water or on a diseased tooth, by the aid of a solar microscope, as sponges, corals, polypi, intestinal worms, hydatids, &c. &c.

Natural history as yet does not furnish satisfactory information on the mode of the procreation of this obscure class of animals. Some are hermaphrodite, as the sponges, and propagate like flowers; others, such as the polypi, are propagated by parts or prolongations, as a great number of plants, which, when cut in slips or parts form new beings; and, finally, there are others which are reproduced by eggs, such as intestinal worms, and hydatids.

The eggs of these animals, and especially of hydatids and the aqueous worms, are so minute, that they are said to pass from one individual to another in the process of generation, to circulate in the blood, and be deposited in the substance of organs, in which they are capable of germinating and transforming themselves into living animals of greater or less size, which are more or less injurious to health. These parasitic animals are found in the stomach, bowels, liver, spleen, lungs, brain, bones, &c. &c., in which they occasion fatal diseases. Living hydatids have been found in all tissues in the body, and also in the brain, liver, and other organs in sheep. A late writer, Mr. Buchanan, describes worms which he found in the blood; and the fact has been recorded, that worms exist in the bowels of the fœtus in utero. Now, when we consider the envelopment of the infant in membranes and the womb, as well as the other impossibility of the worm passing into the stomach, we must conclude that they must have been transmitted by generation.

Moreover, the existence of hydatids in the substance of the liver, brain, bone, &c., cannot be accounted for on any other principle, except the generation of such animals in such tissues. This fact is not refuted by the host of evidence brought forward by the learned Dr. Good, in his *Study of Medicine*, in favour of the ingestion of the ova or eggs of worms from without, in various aliments and drinks. Dr. Tiedemann accounts for parasitic animals by spontaneous generation. (*Treatise on Physiology*, &c., translated from the German by J. M. Gully, M. D., and H. Lane, M. D.)

Green fruits and herbs favour, on account of their humidity, the development of parasitic animals. It is for this reason that we so often observe worms, the lumbrici, ascariides, and tœnia, in persons who take too much green fruits, more particularly in children. Hence the medical proscription of unripe fruits.

SECTION II.—INSECTS.—Insects are considered so insignificant by most persons, that few, unless naturalists, have sufficiently observed the phenomena they present. In these, however, there are separate and distinct sexes, organs which prepare the generative fluids, a real and visible copulation, a greater or less number of eggs, the changes of these into animals more or less perfect, mutations and transformations of these animals until they acquire their complete development, with many other curious and interesting considerations. Such are the facts which the silkworm, the butterfly, the bee, the fly, the spider, even those parasitic animals which are sometimes found on the surface of the human body present us.

Sex of Insects.—There is a glandular body (testicle) in the abdomen of the male insect, supplied with blood-vessels, and destined to form a fluid, which is conducted by a tube (vas deferens) to a small bladder (vesiculæ seminales), from which another small tube (ejaculatory canal), which conveys the reproductive fluid to the female organs. It is easy to observe near the anus of the butterfly, bee, wasp, and other insects, a small elongated body which is capable of erection. There are, however, exceptions in certain insects, as the male spider, for example, in which the sexual organs are near the mouth, and in some others under the abdomen.

We also observe a perfect genital apparatus in the abdomen of the female insect. It consists of a glandular body (ovary), destined to prepare a number of eggs, which are finally to be transformed into new beings. The ovary opens by a canal (vagina in animals, style in flowers) near the anus, and this tube is destined to convey the male seed during coition, to the eggs in the ovary, and to transmit these, after fecundation, into the world (parturition).

In most females there is a canal of greater or less length, terminated by a point, in which there are beds for the eggs. There

are also other distinctive characters of the sexes. The males are in general smaller, they have antennæ (horns), are knotted, possess beard or hairs, which are not recognized in the females of the same species. Certain others have wings, while the females have none, or very small ones; the male is often grey, the female white. There are some insects, such as bees and certain ants, which are incapable of reproduction, on account of the imperfection of their sexual apparatus. These are neuters, mules, or hermaphrodites.

Puberty of Insects.—It is when insects have arrived at the period of their development and strength that they deliver themselves to the act of reproduction; and this epoch arrives, in general, every year, at least in our climate, at the return of spring and before autumn. Then, the larvæ of the caterpillar, which were worms, acquire the beautiful forms which we so much admire in the various butterflies. Their sensibility and their contractility acquire the most sudden and extraordinary development. All their movements are performed with extreme agility; they are in a state of continual agitation; they search with ardour for the act of reproduction; they appear to wish to compensate, by the rapidity of their actions, for the short duration of their existence. It is, however, impossible to conceive the functions of insects without a preliminary metamorphosis through which they must pass before the brilliant epoch of puberty.

Metamorphoses of Insects.—Flies, bees, wasps, butterflies, and an infinity of insects which we see flying in the air, and ardently delivering themselves to the pleasures of reproduction, have not acquired this perfection at one period but by a series of mutations, which are termed metamorphoses. The silk-worm affords a familiar illustration of these mutations. The first state of these animals, as in all insects, is eggs, deposited by the female in a favourable situation for their development. They generally require six months to expand into living beings.

The first products of the eggs are very small, elongated animals, resembling worms, except that they possess sixteen spots like those on the leaves of the mulberry tree, which enlarge with great rapidity.

The insect is now called larva, caterpillar, or silk-worm. The insects which we see in cheese, bacon, &c. are larvæ of flies and other insects in the first stage of their existence*. The larva rapidly changes its skin four times, and then forms a bed or tapestry of silk, in which there is an oval opening. This habitation preserves it from being injured by other insects or foreign bodies, and is called a silken shell or follicle. On dividing these shells we see the larva. Thus

surrounded by this shell, the larva soon throws off its fourth skin, and assumes a new form called nymphæ, chrysalis, aurelia, &c. In about three weeks after this change, the aurelia assumes a new and its last transformation, which renders it totally different from its primary states. It now becomes a perfect insect, of a white colour, which rapidly escapes from its habitation; it flies into the air by the aid of its four wings; it speedily seeks the other sex, and turns its short existence after copulation to the best account, as it dies immediately. Such is the ordinary mode of development of the greatest number of insects which fly in the air, including the species of butterflies, which amount to 1500. All insects do not pass through such complete transformations, even among the winged tribes. Thus, in aquatic grasshoppers, crickets, flying bugs, &c. the larvæ acquire only the new skin and wings which they wanted. Other insects only experience slight changes in their skin, either by renewing the skin or changing the colour: thus ticks, mites, hand-worms, fleas, crablice, spiders, &c. observe these laws; but it is superfluous to enter into more minute details.

Copulation of Insects.—These, like all other living beings, cannot perpetuate their species unless by copulation and the emission of seed. As in plants and higher animals, the spermatic fluid of the male is ejaculated into the organs of the female, and transmitted to the ovary, whose eggs it vivifies.

At the return of spring, when the surface of the earth is warmed and re-animated, the innumerable tribes of insects are roused from their torpidity and hibernation by the rays of the sun, all are impressed to pay their tribute to the goddess of love, and of regeneration. The spermatic odour of flowering plants exalts the amorous impulse of insects, and all animated nature multiplies and reproduces. We may now observe a vast number of insects in the act of copulation, butterflies, common flies, &c. &c.

Male insects are much more numerous than females, but after fecundation they lose their vigour and perish. It often happens that the male expires immediately after having paid his tribute to nature, and in other instances, he is put to death by the female, which surpasses him in strength and vigour, which I have often observed among domestic flies, spiders, &c. &c. In other examples, as among bees, the male and female unite and act in concert for the physical education of their little ones, which they deposit in a place of safety, and defend them from all aggressors and injuries.

Deposition of Eggs of Females.—Almost all insects are oviparous, that is to say, are reproduced by eggs. These require six or seven months for transformation of larvæ into insects. Others are fully developed in a few days, and many require the lapse of

* There is a vast deal of information on this point in Good's Study of Medicine.

years. There is also a great variety in the months of the years in which these transformations take place. In the greater number of insects and in temperate climates, the greatest number of transformations occur from the month of June to the month of September, though there are some in winter.

Most insects perish immediately after copulation, but there are some, as spiders, which survive and propagate for several years.

(To be continued.)

Foreign Medicine.

Heat of the Organs.

MM. BECQUEREL and Breschet have instituted a series of experiments on this subject, the conclusions from which are as follows:—

1. There is a palpable difference between the temperature of the muscles and of the cellular tissue in man, and lower animals, and this seems to depend on the external temperature, or the manner in which the individual is clothed, &c. In man the muscles exhibit differences of temperature, varying from 2 deg. 25 min. C. to 1 deg. 25 min. Living bodies are, therefore, in something of the same condition as lifeless bodies, whose temperature has been raised, but is undergoing a continual cooling from the circumambient medium. This cooling affects the animal layers from without inwards.

2. The medium temperature of the muscles of three young persons, 20 years of age, was found to be about 36 deg. 77 min. C. Davy found the human heat in general to be 36 deg. 66 min. Despretz, for the medium temperature of nine men 30 years of age, found 37 deg. 14 min.; for that of four men 68 years old, 37 deg. 13 min.; of four youths above 13 years, 36 deg. 79 min. The result obtained by Breschet's and Becquerel's new method will be seen to be nearly the mean of the temperature obtained by Despretz and Davy, by means of the thermometer.

3. The medium temperature of the muscles of several dogs is 38 deg. 30 min., whilst Despretz assigns 39 deg. 48 min. as the temperature of that animal. This difference of more than a degree induced Breschet and Becquerel to repeat their experiments several times, but they never got as high a temperature as that given by Despretz. They remark, that the temperature of the muscles changes in a marked manner with the individual state of health, by which the slight variations, in one individual observed, may be accounted for.

4. In the dog, the temperature of the chest, of the abdomen, and the brain, is actually the same as that of the muscles.

5. The common carp exhibited a difference of only half a degree between the tem-

perature of its body and that of the water it swam in.

The repeated contraction of a muscle raises its temperature at least half a degree. Continued violently for some time, the elevation is sometimes more than a centigrade degree. On the other hand, the compression of an artery going to muscles, lowers the temperature of them by several tenths of a degree.

MM. Breschet and Becquerel purpose, in a future memoir, to state their measurement of the temperatures of arterial and venous blood, as well as of the different parts of human and other animal bodies that are not in the normal condition.

—o—

Identity of Grenadine and Mannite.

MM. Latour and Guiart, from close observation of the physical and chemical qualities of these substances, have come to the conclusion that they are identical. The details of their experiments and reasoning are contained in the *Journal de Chimie Medicale* for the present month.

—o—

Cæsarean Operation.

WE learn with pleasure from Dr. Joseph G. Nancrede, of this city, that the patient under his care, upon whom Professor Gibson performed, on the 25th of March last, the Cæsarian section, continues, up to this day, the twenty-sixth since the operation, to improve daily. The wound has closed entirely in about two-thirds of its extent, the remaining third presenting yet a granulating surface, which every day diminishes in size. The mother sits up in bed, and in a day or two will be enabled to leave it. Her babe, which is a fine and healthy one, she nurses entirely herself. Dr. Nancrede promises for our next number a detailed account of this very interesting case.

P. S. Since the preceding was in type, we have, by the polite invitation of Professor Gibson, visited with him and examined this patient. She came down stairs to receive us, and except a little weakness, was in the enjoyment of her ordinary health. The wound is cicatrized, and she states, has been so for some days. The child has every appearance of perfect health. It is now thirty-nine days since the performance of the operation, which must be considered as entirely successful.—*American Journal of the Medical Sciences.*

LITERARY NOTICE.

We are happy to hear that a translation of M. Raciborski's *Manual of Auscultation* is now in the press, and about to be published by M. Bailey, of Cornhill. The translation is by Dr. Fitzherbert. Such a work is most desirable, when we look at the effete nonsense that has appeared in the shape of English Manuals on the same subject.

LECTURE X.

Inflammations of the Pneumogastric Mucous Membrane—Ophthalmia.

IN treating of the inflammations of the openings of the pneumogastric mucous membrane, we shall commence with the external sensitive apparatus.

Inflammation of the Eye.—In the eye the sympathies of inflammation are seen in the most palpable form, and they are divided into organic and those of relation. The transparency of the organ frequently allows us to follow the progress of sub-inflammation when established there, and, *à fortiori*, that of the highest degree of sanguineous inflammation: propagation is there observed in the most ready manner—in short, it is one of the most instructive studies, because it is applicable to internal inflammations.

Inflammation occurs in the external membrane or conjunctiva, when it is known by the name of ophthalmia or conjunctivitis, and may be either acute or chronic. It is also exhibited in the internal membranes of the eye, and may thus be purely membranous, that is to say, occupy the iris alone, the membrane of the anterior chamber, of the lens, of the vitreous humour, of the choroid, or of the retina. It is possible for it to exist in each of these tissues; but this is rare, their contiguity allowing of its ready passage from one to another. It may present itself in a phlegmonous form, occupying and confounding all, and easily recognized by a general sanguineous injection. It may be chronic in each of the membranes, and it is only in that form that it remains for a long time isolated; for when it is acute, its rapidity soon causes it to invade several tissues. For the phlegmon, it also may be chronic, or at least a chronic inflammation

of the cellular tissue of the eye may exist.

All the above are characterized by the four phenomena of inflammation, when it is sufficiently intense.

The causes merit the utmost attention. Generally speaking, I attach great importance to causes: the study of them it is which makes the true savant and the practical physician; by this it is that medical men, of profundity and substantial information, are recognized, while those who neglect them are nothing more than superficial and uncertain practitioners.

At the head of the causes of ocular inflammation are placed external violence, falls, wounds, and surgical operations; those that relate to the function of the organ come next, and I trust that you will shortly arrive at the conviction that the excessive action of a function leads to the inflammation of the organ that performs it. Thus, too strong light will rather inflame the eye than any other organ, than the skin, a mucous membrane, or the cellular tissue, because the eye is made for the light, and receives its immediate stimulation. A forced labour of sight, especially at those periods when sleep is requisite, will irritate the organ. In the torturing amputation of the eyelids, practised among some barbarous nations, the excitation of the eye by light being continual, an excessive ophthalmia is induced, and is propagated to the brain, causing encephalitis. Night work, therefore, is hurtful to the eye, not exactly because artificial light is adverse to it, but because the labour is undertaken at the expense of sleep. Moreover, vapours may exist in the air that are capable of producing inflammation, not only of the mucous membrane of the eye, but also of the throat and other organs; of this kind are the miasms that sometimes rise from marshes, and have no action on the skin, but produce ophthalmia. This inflammation is sometimes caused by irritating gases, by the ammoniacal vapours of water-closets, by the smoke, chlorine, and gaseous acids of laboratories, by the fine dust and sand carried along in the air, by the reverberation of a blazing fire or furnace, as happens in certain

occupations of life. You have also the influence of the other organs, but these are not numerous; that of the stomach, and sometimes of the brain, are the most prominent. As regards the causes of propagation, they are found in those cases where cutaneous phlegmasiæ determine ophthalmia. It is often produced by the inoculation of the pus of an urethritis. In several eruptive phlegmasiæ, such as variola, scarlatina, measles, the inflammation may also be communicated to the eyes.

A peculiar predisposition innate in certain families where inflammations of the eyes are frequent, sometimes favours the action of these different causes. Another predisposition is that which is kept up by a state of habitual superexcitation and plethora in persons who lead an active life, eat and drink freely, and, above all, take great quantities of coffee, brandy, and other spirituous liquors. Occasionally ophthalmia is induced by the suppression of a sanguineous evacuation, especially in women and young girls. Hæmorrhages from the eyes, vicarious of the menses, have even been witnessed—a rare case, however, and of which we shall speak under the head of hæmorrhage. I do not particularize snow as a cause, inasmuch as it refers to the action of light, acting as a strongly reflecting surface to the luminous rays.

In its development this phlegmasia is not ushered in by the general preludes announcing an alteration in the economy; it is manifested without any internal antecedent disorder. The symptoms of it are a sense of heat, of grittiness as from some rough surfaced substance between the eyelids and the ball of the eye, with some degree of itching. The heat rapidly increases, and lachrymation comes on, the tears being acrid, burning, and alkaline. When the inflammation is primarily in the interior of the eye, there is a sense of fullness, heat, and shooting; a small reddish spot or opacity is observed, and the iris is contracted; if more acute, the patient feels the ball as if of fire, a deep seated pain, a lancinating tension, especially when the nervous parts of the organ are affected.

Phlegmon of the eye is rarely primitive, or when it is so it is as a consequence of a blow, of some external violence, or the operation for cataract. It is sometimes accompanied with such an intense congestion that you behold nothing but a sanguineous mass, with the most decided characters of the most violent phlegmasia, as redness, tension, excessive sensibility, &c. Partial phlegmasia of the ocular membranes may transform into phlegmon when there exists a great inflammatory disposition. In this particular there are vast differences in a number of persons attacked with the same inflammation; there are some so predisposed as that their organs are attacked with frightful rapidity, so as to make one believe

the disease in them different from what it is in others; it is the same, however, in fact, and only differs in degree: the approximation of facts, and the study of causes and predispositions will convince you of this truth. What I say here of the eye is found to be exactly the case in internal inflammations, and I have already remarked upon it in the instances of external phlegmasia, such as erysipelas, phlegmon, &c. There are some individuals whom inflammation only, as it were, ruffles, or who resist its violence, whilst it destroys others with astonishing rapidity. It is a phenomenon of infinite degrees, from the most benign to the most outrageous: if you make an entity of each one of them you will only again plunge medicine into chaos; a separation should only be made when a specific cause is observed, to which a specific remedy can be opposed.

But we return to the inflammation of the eye, and behold how it is propagated when once lighted up; from the conjunctiva it may pass to the lachrymal puncta, into the lachrymal sac, and, by the nasal duct, descend to the nose. Sometimes it invades the transparent cornea, which is of a drier and less inflammable temperament than the conjunctiva: it must, however, be exceedingly intense if that occurs. Yet it may go still further, and penetrate within the eye, if not arrested, and if the individual is predisposed, phlegmon is the result—a rare one, I grant, and the more so, because, as I have already remarked, the secretory organs and mucous surfaces have a means of disgoring by the medium of the fluids they give out, by which inflammations are prevented from being propagated within, as they are in turgid tissues and surfaces that have no emunctory. On the other hand, inflammation being first developed in the interior of the eye, may entirely occupy it; but it is scarcely ever seen to pass from thence to the conjunctiva, the sclerotica appearing to act as a barrier against it.

The sympathies are first of all exerted on the muscles of the eye and eye-lids; you see the latter close to preserve the eye from the pain inflicted by the light—a purely instinctive movement, for the will resists it when the irritation is yet slight, but, so soon as it becomes great, the will is powerless. Further on you will observe the parallel between these influences and those that are exercised on the muscles of the splanchnic cavities by the phlegmasia of the viscera. I reiterate the fact, that so long as inflammation is not intense, the will is capable of preventing the semi-instinctive muscles from yielding to the pain; but when excessive, the will loses its power, and we are obliged to contract the organ; this important physiological fact may serve you as a diagnostic means in internal and external pathology. The motor muscles are also forced to act in concert with those

of the eye-lids, in order to turn it from the direction in which the light would come to hurt it. However slight the ophthalmia, the secretion of the lachrymal gland is instantaneously augmented, and if the inflammation increases, the composition of the tears is changed. These are the organic sympathies and the sympathies of relation.

An important influence on the brain is also excited in consequence of the proximity of the eye, and the quantity of nerves and vessels going from one to the other, and affording a ready passage for propagation, so ready, indeed, that intense ophthalmia always place the head in jeopardy of an actual inflammation.

The influence of ophthalmia on the stomach is not well marked, whereas that of gastritis on the conjunctiva is considerable. I have paid great attention to this fact, and have not been able to ascertain that ophthalmia derange the stomach in a special manner; I do not, however, deny it.

On the lungs no influence is excited, unless there be a phlegmon of the eye, in which case, as the cellular tissue of the orbit is implicated, together with the ball of the eye, fever and disturbance of all the functions may supervene, as in other phlegmasia.

You must not calculate on a favourable spontaneous progress in inflammations of the eye. The more we advance in pathology, the more multiplied examples will be found of inflammations that cannot be left to themselves, and against which art must be called in. This is, no doubt, adverse to the old theories about autocratism and the vis medicatrix, but is not therefore less true. Ophthalmia, however, sometimes get well spontaneously, by hæmorrhages that had been suppressed and return; such spontaneous cures are possible, especially in females or young persons having a disposition to epistaxis, but are scarcely ever seen under any other circumstances. Hemorrhoids are rarely critical in inflammations of the eye; nor are they resolved by intestinal evacuations, nor by sweatings. It is only, therefore, in cases where they are the effect of the suppression of an evacuation in youth, when nature readily brings on hæmorrhages that we can expect to see a favourable crisis and spontaneous solution of them. Their progress is not towards a cure, but rather towards disorganization; there is, in the first place, phlegmasia and propagation, then alteration of the tissues, thickening of the membranes, ulceration, rupture, purulent collections, &c.

I return to what most usually occurs in the event of the disease not being extreme; for it is difficult to find instances of ophthalmia not treated, that having proceeded freely to disorganization of the eye. They are generally combatted, and their intensity moderated. The conjunctiva, however, sometimes becomes a purulent fountain, and the inflammation penetrates the eye, takes on a phlegmonous or at least subinflammatory form, and

renders the eye completely opaque, filling it with a caseous or tubercular secretion. It is also possible for the globe of the eye to be converted into a blood-red mass, or to suppurate. Red induration, white induration, opacity of the eye, suppuration—each and all of these terminations is determined by the degree of inflammation and the inflammatory predisposition. But conjunctivitis, even when violent, rarely goes so far; most frequently it confines itself to the production of small abscesses, or when its development is rapid, it shows a puffed border around the cornea, which appears as at the bottom of a vista of swollen, red flesh, that is skirted by the eyelids; this is called *chemosis*. In this case, after some time the cornea itself may become changed into a kind of swollen, injected flesh, and undergo a species of suppuration. It sometimes is pierced, and the aqueous fluid is evacuated; at the same time the iris also sometimes protrudes. In other cases, there is only communication of the inflammation to the membrane of the anterior chamber, where a pus, resembling opaque serosity, forms. If after a certain time no alteration occurs, absorption takes place, and it has only been a minute, extremely limited phlegmasia of the serous membrane.

If the ophthalmia is chronic and has proceeded with less intensity, it does not produce so many disasters, and only gives rise to a swelling of the conjunctiva and cornea, or a varicose state of the capillary vessels. In some cases the cornea becomes entirely opaque, so as to render the passage of visual rays impossible, or to admit only a very few of them. The sensibility of the eye is sometimes so much exalted, that though there is no decided inflammation, light is almost intolerable, the iris contracts, the eye becomes excessively mobile, and the sight is almost annihilated. At other times the inflammation becoming chronic concentrates on the edges of the eyelids, attacks the roots of the eyelashes, fixes itself there, and produces an excess of ceruminous secretion resembling wax. This affection is very obstinate, and is usually only seen with inflammation, in young lymphatic and particularly scrofulous subjects.

Chronicity also appears primarily in the interior of the eye, without being preceded by the acute stage, in consequence of blows, pressure, long continued head-achs, &c. After a few pains, you behold either in the crystalline lens or the vitreous humour, an opaque point, the effect of an actual irritation or subinflammation, a phenomenon of the same order as that which produces tubercles. I have seen this opacity supervene on ophthalmia a great number of times; when it is in the vitreous humour it is whitish, not the whiteness of the opaque crystalline lens, but rather greenish, more deeply situated than it, and unequally distributed throughout the extent of the vi-

treous humour. I have sometimes seen it begin without any preceding violent inflammation, and what I have heard from practised oculists on this point, confirms me in the suspicion I entertained that all the diseases which render the eye opaque are inflammatory phenomena lapsed into subinflammation. One of them told me, "you may work as you please, but there will be no end to it until the eye is completely opaque or softened and absorbed;" which meant to say that an irritation was incessantly in action, and produced a morbid secretion which was a nucleus tending to raise it to the inflammatory state. And this might happen twenty times, if no care were taken to have recourse to antiphlogistics to combat this irritation, until the eye at length becomes again transparent. This is one of the facts that authorize me in telling you that the study of the diseases of this organ is of the first importance, and that it represents the most complicated visceral apparatus.

The name *glaucoma* is applied to the general opacity of the vitreous humour. That of *cataract* is given to the pure and simple opacity of the lens. It is not always possible to detect the circumstances in which it is manifested; it commonly comes with age, without one being able to give a reason for it. Still there must be one, and renewed attention must be paid to detect it; for how is it that some have this opacity and others have it not? There must be a cause, some state of health or some irritation that explains the difference. Sometimes chronic inflammation of the surface of the eye concentrates in one point, especially in one of its angles, and presents a red ulcerated edge, announcing a tendency to cancerous disorganization. In my idea this is always the effect of bad treatment and the reproduction of the causes of inflammation. Thus it is that you should understand it, and not allow irritations to proceed in an absolute and fatal progress towards cancerous, tubercular, encephaloid, and other disorganizations, but observe the modifications effected in these irritations by the numerous agents that are capable of influencing them; you will then almost always perceive that their disorganizing terminations are owing to the renewed action of the old irritating causes, or of new ones, at the time when nature was tending to resolution—a consummation which those causes prevented.

The modifications of the sensibility are very various in these different affections. When the inflammation is acute the sensibility is excessive; and when chronic the same feeling exists in a feebler degree so long as there is no opacity. Sometimes the sensibility of the eye prevents it from exercising its functions, though there is scarcely any inflammation; this is a shade of disease in which the nervous tissue is affected with a predominance. When subinflammation has produced mischief with a determined

hand, no further sensibility of the eye remains, and it becomes a sort of foreign body resembling an indurated gland. As however it still contains a great quantity of nerves and vessels, inflammation is often ready to reappear in it.

What has been said may stand for the necroscopy: for we may see without opening. We pass to the prognosis, which in the first place is drawn from the intensity of the inflammation. Persons may be affected with extremely rapid inflammation, and in certain dispositions of the system, such as those exhibited in eruptive diseases, disorganization is ever imminent. It has also been remarked, that ophthalmiae, following on urethritis, are exceedingly rapid in their progress, and readily suppurate. You must therefore regulate your prognosis of the rapidity of the disease, and the danger of disorganization, not only by the inflammatory aspect of the organ, but also by the concomitant disease, by that which has preceded it, and by the predisposition. When a conjunctivitis becomes chronic, we have to fear disorganization of the membrane and of the transparent cornea, the latter of which may be perforated or externally opaque, or else the inflammation may penetrate internally and be followed by opacity. If there is a suppurative tendency we have everything to fear; if there is only a simple varicose condition, the disease may be endured for a long time, and finally lapse into a lachrymation and an extreme ocular sensitiveness—the latter may be so excessive as to cause contraction of the iris during the day, and vision only at night: this is *nyctalopia*. There is every reason to expect a cure of this neurosis if there is no disorganization, or even if the organ is slightly atrophied without opacity and alteration of the brain; but if the irritation is such as tends to the opacity of the humours, the case is serious, particularly if this irritation resides in the vitreous humour. There is less mischief in the lens, because, being an isolated body encased in other humours, it suffers and changes within a smaller limit, whereas, when the tendency to opacity is in the vitreous humour, which fills almost the whole expanse of the ball, that expanse is the wide limit, and requires a longer period for its entire occupation, during which the patient is always exposed to a fresh start of the ophthalmia towards the acute stage. Add to this, that there is no curative operation for the opacity of the vitreous humour as there is for the crystalline lens.

In the internal parts you have only to consider in the prognosis the state of the stomach, and the suppression of hemorrhages, except in very intense ophthalmia, when the inflammation is propagated to the brain. Should you be called to those who have had the misfortune to lose their eyelids, you must expect the speedy development of a cerebral phlegmasia.

As regards the treatment, we must suppose ourselves in all the positions we have described. If we are aware of the suppression of some sanguineous evacuation, we must first of all recall it, or replace it by bleedings. The point of a suppressed eruption must be treated with the stimulation of a blister or some other irritant. If the ophthalmia is only imminent, or in its first degree, and the action of light is feared, we must order darkness and quietude; the efficacy of this I testified in my own person, when traversing mountains covered with snow, when on my way to Spain, in 1809. Ophthalmia came on, and on arriving in the evening at my lodging, I was located in a house filled with smoke, which quickly added to the activity of the inflammation. It was my duty to start the following morning, and it was therefore essential that I should rid myself of the complaint with as much expedition as possible. I had recourse to the brutal revulsive treatment; I laid on my back, ate nothing, and dropped vinegar into my eyes, from which I suffered horribly: at the same time it obliged me to keep my eyes closed all night, and on the following morning the ophthalmia was reduced, and I was enabled to go on my way. I had previously used this means, or else astringents in incipient ophthalmia. When I was a naval surgeon, I found them successful when the disease was only in the birth, but not when it had reached its fulness. This local stimulation, which is frequently curative when applied à propos, is what I call counter-stimulation, an expression very applicable to the employment of irritants on the irritated spot itself, whereas that of revulsion agrees better with the action of stimulants on some point, other than that which the irritation occupies. Anti-ophthalmic counter-stimulation is produced by means of astringents, vinegar, acetate of lead, sulphate of zinc, or of iron, tannin, &c. But how are we to explain the cure of an incipient ophthalmia by water that is almost at the boiling point? lachrymation follows, and the cure is the result; it is the lachrymation that effects the cure. At other times alum is mixed with white of egg; this is spread on lint, and placed over the eye; such counter-irritation succeeds wonderfully, and it is hard to say at what point the conjunctiva would cease to tolerate such stimulants. But their success depends on an instant, as it does in urethritis similarly treated; they fail when the inflammatory disposition is decided, or the disease is already advanced. Recourse must then be had to antiphlogistics, to bleeding if there is plethora, or threatening congestion of the

brain, and to similar treatment of the gastric passages if they are irritated, or to purgatives if the patient is at the same time plethoric and stercoral. Local bleedings are highly efficacious, but leeches should not be placed on the conjunctiva itself, for I have seen serious consequences, and the loss of the eye itself, ensue upon it. They should be placed around the eye, and in sufficient numbers to obviate the renewal of the inflammation, especially if we have reason to fear the disorganization of the organ. At the same time we order severe diet, purgative clysters, and irritating pediluvia; the eye is bathed with cold astringent collyria, or with ice, if the eye can bear it. If you do all these in quick succession, and without loss of time, and particularly if you repeat the leeches with propriety, you cannot fail to put a stop to the disease. But if you act tardily, or only use slight means, an abscess may form underneath the conjunctiva, or in the cornea, the eye may be perforated, or the inflammation penetrate internally.

Emetics have been advised against ocular phlegmasiæ: but I do not think them advantageous; they cause congestion of the head, and it is better to stay by purgatives.

When ophthalmia has become chronic, we must see whether there is not still an opportunity of using local bleedings that may have been neglected, and then employ topical means according to the state of the eye. If it is very sensitive, we may employ anodyne aqueous collyria with advantage, as those of opium and belladonna. If the susceptibility is not much exalted, and there is a varicose tendency, astringents are preferable, as at the onset of the disease. If the inflammation is fixed in the eye, and tends to disorganize it and render it opaque, as well as to reproduction, we must not only repress it by antiphlogistics as far as possible, and employ mucilaginous, demulcent, and opiate collyria, but also have recourse to issues, blisters, cauteries, moxas, &c., taking care not to be too tardy in using them, and not to exhibit a temporary timidity: many a cure fails from this cause.

An inflammation confined to the eyelids and not acute, is advantageously treated with camphor cerate, as Chaussier used to do. More active ointments of the oxide of lead, of mercury, &c. are used. To these means revulsive ones are added, and a cure is obtained in the majority of instances. For the rest, the success is always proportioned to the intelligence and perseverance with which the antiphlogistic, counter-stimulating, and revulsive treatments, are combined and conducted.

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

By DR. RYAN.

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;*

Session 1834-35.

LECTURE XLVI.

*Diseases of the Intestinal Canal developed after
Birth, continued—Tormina—Griping—Colic
—Inward Fits—Flatulence—Flatuosity—
Acidities in the Stomach and Bowels—
Diarrhœa.*

GENTLEMEN—I shall now continue the description of the disorders of the bowels.

Tormina, Gripings, Pinchings in the Bowels, Spasms, Colic, and inward Fits.—These precede or often accompany constipation, but are induced by a multiplicity of other causes. They have been ascribed by the vulgar to the longings, fears, and gripings of women during pregnancy, to the absence of after-pains, or uterine contractions after delivery, as if there were any direct connection between the digestive organs of a pregnant woman and those of her infant after birth; or between the womb of the one, and the bowels of the other. Experience and observation have proved that nothing so disposes to gripings, &c. of infants at the breast, more than their voraciousness which will scarcely allow them to quit the nipple; and this induces them to take too much food, which irritates their stomach and bowels.

Other occasional causes of this disease, are the errors in diet and the mental emotions of wet-nurses. Every experienced practitioner is aware of the fact that salted meats, crude vegetables, cabbages, turnips, parsnips, carrots, salads, &c., unripe fruits, ardent or fermented liquors, brandy, wine, gin, whiskey, rum, &c., ale, porter, &c., in excess, excessive labour or fatigue of any kind, want of rest during the night, as well as moral emotions, including all the passions, fear, terror, jealousy. &c. &c., will injure the breast milk, and this will cause gripings, diarrhœa, jaundice, and even convulsions in infants. It is impossible for women under the influence of these causes to form good chyle, good blood, or healthful breast-milk. We can easily conceive then, that the milk may be of a bad quality, more indigestible, less nourishing, and more irritating than when healthful. Hence the derangements, the flatulence, or wind or gas in the bowels, and above all the acidity in the bowels of infants, evinced by green, brown, white, offensive motions; hence the gripings, "pinchings in the

bowels," and unnatural motions of infants in many cases, though these arise, perhaps as often, from the artificial food which is almost universally given to them. I have already described the errors committed by parents and nurses in feeding infants, and I must once more observe that they are common, indeed almost universal.

These complaints are most frequent during the first four or six months of the infant's life. This is easily accounted for, by the highly sensitive and irritable state of the stomach and bowels of the infant at this period of its age, and by these parts losing their sensibility as the development of the body advances. These spasmodic gripings are only occasional, they cease and are frequently renewed, and cause the infant to cry, and to be deprived of sleep. The abdomen becomes tense, unequally contracted, especially about the navel, as in the colic of adults, which symptom is produced by the contraction of certain portions of the recti muscles, the gas or wind rumbles in different parts of the intestines, excites irritation, spasm, or inflammation, there is constipation or diarrhœa, the motions are greenish and curdled, and often of various colours, and they exhale an odour which practitioners recognize as characteristic of acidity in the primæ viæ, or intestinal canal; or they may be extremely offensive or fœtid. During the violence of the pain, the infant draws up its legs, kicks violently, writhes its body from suffering, the belly is tense and elastic, and if the fore finger or middle of the left hand be placed upon it, and the nail of this be struck with the point of the right fore finger, a hollow tympanitic sound will be heard, which proves there is a quantity of gas in the bowels.

It is erroneously supposed by some practitioners, that the distention of the stomach and intestines with gas is always caused by the infant's swallowing atmospheric air, when it sucks or takes food; but the gas found in the intestinal tube differs from atmospheric air in its chemical properties, and is a secretion. This fact has been attested by continental chemists who collected and analyzed it; and they conclude that it is very different, in different portions of the bowels. When infants die of gripings with distention of the bowels, there is often no trace of inflammation discoverable; and the only morbid appearance is a large collection of gas in the intestines.

Treatment.—When called to cases of this description, we should first examine with care into the cause of the disease, so as to be able to combat it with success and prevent its return. We should therefore ascertain the regimen and habits of the nurse, the constitution, and artificial diet of the infant, as these are, in general, the sources of the gripings and colics of young infants.

We should next apply dry heat to the

stomach and bowels, by means of warm bran, salt, or chamomile flowers placed in a soft flannel bag, and order the abdomen to be rubbed with the warm hand or with flannel. This plan will often afford relief; but should it fail, we should order the infant to be immersed in a warm bath, or the abdomen may be fomented with warm water or a decoction of poppies and chamomile, or rubbed with an anodyne liniment, as the camphorated, with laudanum, in the proportion of an ounce of the one to a drachm of the other; after having relaxed the distention of the stomach and bowels by these means, we should employ proper remedies to evacuate their contents. A tea-spoonful of castor oil, with one drop of oil of anise-seeds and one, two, or three of laudanum will be generally successful. The contractions of the intestines caused by this combination of medicines will often excite a free motion, and the expulsion of gas. An infusion of carraway or coriander seeds, of cinnamon bark, or of other carminatives may be employed to expel the flatulence or gas. A small quantity of some narcotic may be added with advantage, according to the experience of George Armstrong, Underwood, Doublet and many other writers. Opiate clysters are also beneficial, as starch and laudanum. A few drops of tincture of asafetida are also useful when children are subject to repeated attacks of colic or griping. It should also be borne in mind that a long continuance of pain, for example, for three or six hours, in defiance of all remedies, may terminate in inflammation of some portion of the bowels, or in convulsions. It is an axiom in pathology, that temporary or transient pain in any part is characteristic of disordered function, and may in general be relieved by the internal and external use of sedatives, opium, morphia, &c.; but when the pain becomes constant, the skin hot, the pulse rapid, and feverish symptoms are evident, then inflammation is present, and requires blood-letting both general and local. This rule applies to children and adults, and must never be forgotten by medical practitioners. The pain in colic is relieved by pressure, the pain in inflammation of the bowels is aggravated, and the patient cannot bear the slightest touch. The diagnosis of intestinal inflammation has been described in a former lecture, and should be carefully remembered. Some prefer the almond or castor oil, or olive oil, to which others object, on account of the rancidity which they readily acquire in the bowels. I am not quite satisfied that this is a valid objection.

The prevention of the recurrence of this disease consists in removing the causes in the nurse or infant. It will be necessary to regulate the regimen of the first, and render it conformable to the rules of hygiene already laid down; and we should advise aliments capable of furnishing a health-

ful milk, such as is easily digested. The indication of treatment as regards the infant is to improve the digestion by means of mild tonics, such as the infusions of rhubarb, orange-peel, mint, or syrups of quinine, iron, &c. &c. These are to be given at first in very small doses, and gradually increased. They should be sweetened with sugar, honey, treacle, or liquorice, or may be given as lozenges.

Most infants subject to constipation, gripings, and colics, suffer very much from acidity in the first passages or stomach and bowels, and this is best corrected by magnesia, prepared chalk, or crab's eyes, liquor, carb. potass, chalk mixture, lime water, &c. In such cases I order milk to be diluted with lime water, as a common drink, and the other medicines to be made into lozenges. These absorb or neutralize the acids, form neutral salts, which purge the infants. The infant should wear a flannel roller round the abdomen, and its lower extremities ought to be kept warm by woollen clothing. Flatulency is in general only a symptom, but it sometimes becomes a real disease: I shall therefore describe it as such.

Flatulency — Flatuosity — Wind in the Bowels.—This disease is common to delicate infants, who are spoon-fed or dry-nursed, or when the breast-milk is thin or deteriorated. I have repeatedly known infants who were attacked with griping and flatulence after the nurse had taken crude vegetables, and other flatulent foods.

The symptoms are, tension and swelling of the abdomen, with a tympanitic sound on percussion, made in the manner already mentioned, or with a pleximeter, disengagement of gas by the mouth or bowels, restlessness, crying, insomnia, or want of sleep, feebleness, and general languor, which is often so great that the infant is supposed to be dying. The countenance becomes pale, the eye loses its vivacity, the limbs and body emaciate, a diarrhoea succeeds the constipation, the breathing becomes difficult, on account of the distention of the abdomen, which prevents the due expansion of the lungs and descent of the diaphragm, the face becomes livid or black, or swollen, convulsions supervene, and death very speedily puts an end to the scene, unless proper remedies are employed.

The flatulence is generally situated in the large intestines, and is carbonic acid, carbonated or sulphureted hydrogen gas. It is an unfortunate circumstance, that, though we know the kind of gas, we are acquainted with no remedy which can prevent its secretion. The discovery of such a remedy is still a desideratum. We frequently observe sudden distention of the abdomen, with gas, in the last stage of typhus and puerperal fever, and in abdominal inflammations a few hours before their fatal termination; and this, in general, defies all re-

medies, though it may be removed by the introduction of a tube into the bowels, as advised by Dr. O'Beirne.

Women who have the management of children, attribute several diseases to flatulence or wind in the bowels, as hiccup, vomiting, purging, griping, restlessness, crying, and screaming. They exhibit peppermint water, spiritous drinks, cordial waters, as anise-seed, dill, and cinnamon water. These are rendered palatable, and may be mixed with the food. There is great danger in employing peppermint and spirit of any kind, as these are too stimulating to the sensitive stomach of a young infant, will excite irritation or inflammation, and, instead of curing the disease, will, as Heberden quaintly observes, "dispatch the patient." There is no objection to the other mild cordial waters already mentioned. Flatulence is often a symptom of indigestion, and is most effectually prevented by giving some slight tonics with aromatics, such as infusion of rhubarb, orange-peel, &c. sweetened, the carbonate or muriated tincture of iron in white wine, or quinine in white wine, or in the form of lozenges. The diet of the infant should be nutritious, as the animal and vegetable jellies, gravies mixed with arrow root, a mashed mealy potatoe, a fresh egg, good new milk, &c.

The indications of *treatment*, in cases of infants, are to dislodge the gas, and prevent, if possible, its re-accumulation.

To fulfil the first indication, we exhibit some tonic and carminative medicine, as infusion of anise-seed, dill, mint, with a few drops of sulphuric ether, or oil of turpentine. The following prescriptions may be tried in succession, and are generally successful:—

Rx. Aquæ anethi, \bar{z} j;
Sacchari puri, \bar{z} j;
Olei anisi, m. iv—vj;
Magnesiæ cal., $\bar{\Delta}$ j;
Mucilag. acaciæ, \bar{z} iiij;
Liquor. opii sed., m. iij.

Dosis cochleare min. singulis, secundis vel tertiis horis nisi supervenerit somnus.

If this fail, four or six drops of oil of turpentine may be added, or the same quantity of aromatic spirit of ammonia. To increase the effect, frictions with the warm hand or flannel should be made over the stomach, dry heat applied as before mentioned, camphorated spirit or anodyne liniments rubbed on the abdomen, and then warm baths may be tried.

Professor Dewees, of Philadelphia, has employed the following mixture in colic, "with the most decided advantage; it rarely failing to give instant relief, and sometimes effecting an entire cure."

Rx. Magnesiæ calcin. $\bar{\Delta}$ j;
Tincturæ foetidæ, \bar{z} j;
—— opii, m. xx;
Aquæ fontis, \bar{z} j.

Misce.

"Of this twenty drops are to be given when the child is in pain, and if not relieved in half an hour, ten drops more are to be administered. This dose is calculated for an infant from two to four weeks old." The dose must be gradually and cautiously increased at a more advanced age.

According to this learned and experienced writer, there is a form of colic which is distinctly periodical. It generally occurs from four to six o'clock in the afternoon. It does not affect the health of the infant, who thrives with it, nor does the disease appear to be influenced by the diet of the nurse or infant, and in this it differs materially from the first. It continues for three months, and is called by American nurses "the three months' belly-ache." The child is habitually costive. I have never observed this form of disease in this country, and may add, that its treatment is the same as for common colic of infants. Perhaps it is excited by the extreme cold of the evenings in America, after the intense heat of the days—a transition of temperature which must have a powerful effect upon nurses and infants at the breast. Should all the means already mentioned fail, then a gum elastic catheter ought to be introduced into the bowel, and this will allow the escape of the gas, as my able friend, Dr. O'Beirne, has proved by numerous instances of adults. He has not only recorded numerous successful cases in his work "On Defecation," but informed me, since its publication, of examples of strangulated hernia, for which the usual operation was about to be performed, but which he relieved by the introduction of a tube into the lower bowel. I have since repeated the operation on infants with the greatest success, when all other remedies had failed.

When the face is red or livid, the breathing laborious or difficult, and the signs of cerebral congestion prominent, or when convulsions have supervened, the infant should be immersed in a warm bath, a napkin wetted with cold water applied to the scalp, or a small stream of cold water, from a small tea-pot or mug, poured on the head while the bath is being employed, and leeches applied behind the ears and round the base of the skull, in the proportion and with the precautions already stated. A cold spirit lotion should be constantly applied to the abdomen, with a view of assisting the internal medicines in contracting the intestinal canal, and consequently expelling its gaseous and other contents. I have repeatedly observed the best effects result from cold applications in puerperal peritonitis, and this day, in a case to which I was called by my friend, Mr. Hughes, of Holborn. This practice is employed in Germany, but scarcely ever in this country; at least, I have never heard of it.

The second indication is to improve the regimen of the nurse, by advising her to

avoid every description of flatulent food, and to substitute nutritive aliment, as fresh meats, roasted or boiled, with a moderate quantity of wine, porter, &c.

If the infant is dry-nursed, the diet should consist of those aliments recommended on a former occasion, when describing artificial lactation. Under that head will be found a description of the errors usually committed by parents and nurses in feeding children, which are the fertile source of this and a vast number of bowel complaints.

Inward Fits.—This is a term used by nurses when an infant smiles during sleep, and they suppose that this pleasing appearance is caused by flatulence in the bowels. This is a great error, and one that alarms parents most unnecessarily. I know of no such disease as inward fits, and there is not a single writer of authority, on diseases of children, of the present age, with whose work I am acquainted, who is not of my opinion. The term inward fits is ridiculous, according to modern pathology. I should not have noticed this imaginary disease at all, were it not that nurses are constantly talking about it, and therefore young practitioners should know what they mean by it.

It is absurd to suppose that the smiles of an infant are indicative of disease, or to imagine that wind in its bowels is the cause of them. Every infant has more or less air or gas in the bowels, on account of its sucking so rapidly, or taking common food voraciously, for nature has made it ravenous; and also on account of indigestion, constipation, and the intestinal secretion of gases, to which it is liable. Every healthful infant smiles in its sleep, as observant practitioners have noticed, and it is only ignorant nurses, those of the last century, who ever speak of inward fits — “a term,” says Underwood, “they are ever using, but have no precise ideas of, nor do any two of them intend the same thing. It would be better if the term were altogether abolished, and the word fit used only when the child is evidently convulsed.” Nurses often confound what they call inward fits with convulsions, and employ the same remedies in both, as Dalby’s Carminative, Godfrey’s Cordial, soot drops, assafoetida drops, diacodium, or syrup of poppies, which is sold at public houses in large cities, and composed of a large quantity of laudanum, water and some treacle. As these things cause the dislodgement of gas from the bowels, and cure inward fits, they are, according to the experienced commentator on Underwood’s work, Dr. Meriman, “considered the best possible remedies for all kinds of fits, and are given with an unsparing hand in inflammatory attacks, if there be any resemblance, real or supposed, to fits. It is obvious when such remedies are employed at the commencement of true convulsion fits, they must be extremely prejudicial.” There is not the slightest doubt of the accuracy of this statement; and I may

add, that I have repeatedly known numerous instances of infants destroyed by such nostrums. “If the infant,” observes Dr. Underwood, “should sleep too long, and the smiling should often return, it may be taken up, gently tapped on the back, and its stomach and belly well rubbed by the fire, which is all that can be necessary. This gentle exercise will occasion a discharge of wind from its stomach, and the child will go to sleep again quietly.” The author might have added, that the same exercise will cause the expulsion of gas from the stomach and bowels of a healthy infant, either asleep or awake. Popular views of diseases are often very ludicrous. It is a prevalent opinion among the lower classes of the Irish, that when an infant smiles during its sleep, “it is smiling at the angels,” or as one of the national poets has rendered it, when describing the watchings of an affectionate mother, “I knew that the angels were talking to thee.”

Acidities in the Stomach and Bowels of Infants.—The stomach and bowels of infants are exceedingly sensitive at birth, and very readily deranged by every description of food, unless that intended by nature, the mother’s milk, the milk of another woman, or of some few of the domestic animals. Almost all infants are over-fed by nurses, with a view to make them thrive rapidly. The nurse is not satisfied that the infant is abundantly supplied with breast milk, but she thinks it ought to be constantly fed, or rather crammed with artificial food, almost every hour in the day. She gives it water-gruel, pap, panado, patent barley, biscuit powder, and such like substances, combined with milk, and perchance with some spirituous or fermented liquor. She is not aware that three table-spoonsful of food or drink are sufficient to fill its stomach; she goes on until she fills it to the throat, the infant is then pained, it cries and vomits, and then is again over-fed, “as, poor thing, it is hungry,” when the same symptoms reappear. The incessant repetition of this repletion or over feeding irritates the stomach, causes it to secrete a depraved or acid gastric fluid; and this will curdle any farinaceous substance mixed with milk, which will act as an irritating matter, and cause griping, flatulence, a sour smell on the motions, or of the matter vomited. These are the usual symptoms of indigestion, and are accompanied by acid eructations or expulsion of air from the stomach, vomiting, sighing, moaning, peevishness, crying, green and other coloured motions, and drawing up the legs towards the abdomen. These symptoms are invariably caused by too much food, or by that which is indigestible. The various foods just mentioned are improper, and indeed unnatural, for the stomach of a new born infant. They irritate and inflame the stomach, as dissection has amply proved; for if we examine the stomach and intestines

of an infant who has died of the disease under consideration, we either find their internal surfaces as red as scarlet, or some portion of them destroyed by ulceration. If we bear this fact in mind, reflect on the injury that must be done by the exhibition of ardent spirits diluted with water, or mixed with food, in such cases, we cannot be surprised at the immense mortality of young infants, from complaints in the digestive organs, the stomach, and bowels—a fact already attested in a former lecture. Another error of nurses is the free exhibition of sedatives, syrup of poppies, diacodium, Godfrey's Cordial, Dalby's Carminative, &c. &c. in this disease, which stupify the infant, and prevent it from awaking every two or three hours to take a fresh supply of food. The effect of this plan is, that as the absorbents are in constant action, they remove the substance of the body, as a proper supply of chyle, or the material for new blood is not supplied by the digestive organs, and consequently, great emaciation and debility ensue.

Acidity in the first passages or *primæ viæ*, as the stomach and bowels were formerly designated, is so common, that Harris supposed it the great cause of infantile diseases, and that the earths, such as magnesia, the preparations of chalk, crabs' eyes, or prepared oyster-shells, and lozenges of carbonate of soda, were necessary to neutralize it. These, combined with the acid, formed neutral salts, which purged the bowels. In this as well as numerous other doctrines in medicine, the effect is mistaken for the cause. Constant and repeated irritation of the stomach has excited the acidity, and permanent relief will not be afforded unless the diet of the infant is changed and suited to its age.

The first indication of *treatment* is to remove the cause of irritation in the stomach, by changing the infant's food; and the second, to neutralize the acid in the stomach and bowels. The diet having been changed or modified, we first open the bowels, and then administer the class of medicines called absorbents, such as already mentioned.

The best aperient is rhubarb and magnesia, and the dose must be proportioned to the age of the infant. The following mixture is then prescribed with advantage:—

R̄. Liqueur calcis, ℥ ij;
Liquoris potassæ, m. ij—v;
Magnesiæ calcin., ℥ j;
Liquoris opii sedat., m. iij—x;
Olei anisi, m. iv—vj;
Syrupi simplicis, ℥ j.

Dosis, coctheare min. ter quarterve die, ex lactis recentis, vel jusculi bovini semicyatho.

This mixture will neutralize the acid, relieve pain, and expel flatulence from the bowels. It is also effectual in hiccup, griping, and colic. The alterative powders

mentioned for constipation should be given regularly, and the tone of the stomach improved by bitters or tonics, as the infusions of rhubarb, orange-peel, cinnamon, calumbo, syrups of quinine, iron, &c. The diet should consist of the gravies of roast meat, with a smaller proportion of bread, pap, panado, arrow-root, and other farinaceous substances. A small quantity of tent or sherry wine diluted with water, such as a tea-spoonful in half a wine-glassful of water, properly sweetened, may be given two or three times a day, or half a wine-glassful of ale, porter, or stout, with an equal quantity of water, may be allowed as often in twenty-four hours.

The diet of the nurse should also be regulated, so as to improve the quality of her milk. In some cases the warm bath, frictions with the warm hand, or with flannel, on the abdomen, will afford relief, as in the gripings and colics of children, with which this disease is generally complicated.

Dr. Heberden's plan of treatment deserves notice; but it appears to me, he did not sufficiently appreciate the morbid condition of the inner coat of the stomach, when he proposed it.

"The first object is to open the bowels with rhubarb, and then administer seven grains of prepared oyster-shells, or the same quantity of magnesia, or three grains of chamomile flowers, or powdered calumbo root, or ten drops of the liquor of potass, any of which may be combined with some weak bitter infusion." Dr. Smyth, of Matlock, who translated the work from which I quote (1805), adds in a note, "I once saw a child restored to health after the common remedies had failed, by ten grains of chamomile and three grains of ginger, given twice a day."

According to more modern pathology and experience, the mucous or inner coat of the stomach should be free from irritation or inflammation, before bitters could be used with safety.

Diarrhœa—Looseness—Purging.—This disease consists in frequent motions from the bowels, unaccompanied by fever, attended with much griping, and resembling a murmuring noise from flatulence in the abdomen, and frequently by nausea and vomiting. If the disease is severe, the countenance becomes pale or sallow, there is thirst, which gives rise to a craving for cold drink, the tongue is furred, and there is often rapid emaciation.

In some cases a great quantity of yellow fluid feces are discharged, in others the motions are milky, white, chylous, or mucous, or purulent; and in more the food is expelled unchanged. The dejections may vary in number from one to fifty in twenty-four hours. The proximate cause of diarrhœa is increased peristaltic motion of the intestines, and this is readily excited in infants, on account of the extreme sensibility

of the mucous or inner coat of the stomach and bowels. There is a strong sympathy between the digestive and all other organs and parts of the body, and we are not surprised at the numerous disorders in all parts excited by those in the alimentary canal, or stomach and bowels. Numerous direct and indirect causes irritate the intestines, disorder their vital power, and augment their secretions. These are, improper, indigestible, or acrid food, acid fruits, the deranged digestion caused by bad or depraved milk, oily, mucous, or saccharine substances, as fat meat, honey, butter, pastry, acid fruits, both fresh and dried, abuse of purgatives, the repercussion or sudden disappearance of exanthematous eruptions, such as small pox, measles, scarlatina, &c., the application of cold and moisture to the surface of the body, and especially to the feet, suppressing perspiration, and the secretions of the serous and mucous membranes, acidity in the stomach, redundancy of bile, increased secretion of mucus from the mucous follicles of the intestines, worms, erythematic inflammation, retrocession of gout or rheumatism, dentition or teething, diminished action of the absorbents of the intestines, accumulated and hardened fæces, moral affections, as fear, jealousy, anger, &c., which influence the mother, disorder the breast milk, and affect the infant at the breast. Fear or terror also affect children, and cause diarrhœa. This disease is an intestinal catarrh, according to Professor Capuron, an alvine dejection of mucus or serosity, which mixes with the excrements, and renders them more fluid than ordinary.

The disease occurs at every period of early infancy, but generally about the second or third month. This disease is idiopathic or primary, and ought to be distinguished from others of which it is symptomatic, as the species attendant on dentition.

The motions may be feculent, bilious, mucous, chylous, or consist of the unaltered food. The colour of the dejections varies according to the intensity of the disease. They may be yellow, green, white, brown, or black. Indeed, nurses often state, when asked about the colour of the motions, "They are of all colours." It is supposed that green stools are caused by a redundancy of bile. Their consistence also varies. They may be watery, curdy, hardened, "knotty," custard-like, clayey, &c. &c.

The prognosis will depend on the cause, duration of the disease, the frequency or abundance of the motions, and the danger will be proportioned to the strength or feebleness of the constitution of the infant. The disease often causes great sinking of the vital powers, and may be followed by convulsions, anasarca, &c. It has proved fatal in forty-eight hours, though it may continue for several weeks.

The indications of treatment are to calm

the intestinal irritation and to remove the cause of it.

The first thing to be done is to change the diet, and to order bland drinks, such as barley water, rice, milk, beef, veal, or chicken broth, made very weak, by boiling these articles for a few minutes only, the mucilage of gum arabic, &c.; and to administer clysters of this description, with proper doses of opium or morphia. Two thirds of a wine-glassful of mucilage of gum arabic, thin starch, beef, veal, or chicken broth, with three or five drops of laudanum, may be ordered as a clyster for infants under one year old, as in cases of enteritis, ileo-colitis, or recto-colitis. These are, however, seldom employed in this country, until astringent medicines have been administered, and failed. M. Capuron is of opinion that we should never arrest or suppress diarrhœa suddenly, when it has existed for some time, or when it is habitual. I cannot help remarking, that under such circumstances it is not readily suppressed by any remedy; but a severe diarrhœa of one or two days' duration may endanger the life of an infant, and requires to be arrested or suppressed.

It appears to me, after careful reflection on the sensibility of the gastro-intestinal mucous membrane, or inner coat of the stomach and bowels of infants, that simple and non-inflammatory diarrhœa should be always controlled or arrested by proper astringents, with opiates and cordials. The following medicines will in general afford relief, if the diet be changed, and mucilaginous drinks, such as barley water, linseed tea, or gum arabic dissolved in boiling water, be administered at the same time.

Rx. Misturæ cretæ, ʒ iij;
Confectionis arom., ʒj;
Tincturæ catechu, ʒ ij—iv;
—— opii, m. iv—vj;
Olei anisi, m. iv—vj;
Syrupi simplicis, ʒvj.

Sit mistura, cujus sumat infans cochleare parvum, post singulas sedes liquidas, phialâ prius agitâ.

The intention of ordering this combination is this—the chalk or cretaceous mixture is an absorbent and antacid; it is therefore prescribed with the view of neutralizing any acid in the intestinal canal (bowels); the aromatic confection is a cordial and stimulant, which is required on account of the debility frequently induced by diarrhœa; the catechu or kino, which may be used in the same quantity, is an astringent; the opium a sedative, which will relieve pain, irritation, and spasm; the oil of anise-seeds, a carminative, or a medicine which will expel, as its therapeutic name imports, flatulence, as if by a *carmen* or charm; and the simple syrup, which may be replaced by sugar, honey, or liquorice, is added to render the other ingredients palatable.

The following mixture is recommended in strong terms by Professor Dewees:—

Rx. Cretæ preparatæ, 3 ij;
Tincturæ opii, m. xx—xxx;
Sacchari albi, 3 ij;
Olei cinnamomi, gutt. j;
Aquæ fontanæ, 3 ij.

Dosis, cochleare parvum, secundis vel tertiis horis.

In extremely obstinate cases of diarrhœa, which occurred during the prevalence of malignant or blue cholera in 1832, 33, 34, and this year, I prescribed the following mixture with astonishingly good effects:—

Rx. Cupri sulphatis, gr. 1-12th—1-8th;
Syrupi simplicis, 3 iss;
Tincturæ opii, m. x—xx;
Olei anisi, m. iv—vij.

Dosis cochleare min. singulis vel secundis horis; vel post-singulas sedes liquidas, nisi supervenerit somnolentia, aut somnus.

Drs. Armstrong, Underwood, and Capuron advise emetics of ipecacuanha or tartarized antimony in the first instance, with a view of clearing out the stomach of indigestible or improper food. But when we bear in mind the irritation of the stomach, and the inflammatory redness of its mucous or lining coat in certain forms of diarrhœa, we must perceive the impropriety and danger of this plan. The fact is, that Dr. George Armstrong, one of our earliest writers on infantile diseases, supposed that he made a wonderful discovery, in introducing antimonial emetics, not only in the disease under notice, but in those already described, and many others, of the abdomen; and the two succeeding writers, with many others, have blindly adopted his dangerous practice. Modern pathology has, however, shewn its baneful influence, and it is scarcely ever followed at present. It is now proved, beyond the possibility of doubt, that the mucous membrane of the bowels is red or inflamed in some part of its extent, in fatal diarrhœa. and yet it is recommended to irritate the stomach with ipecacuanha or antimony (which is only a portion of the alimentary canal, and one that sympathises most strongly with every part of the remainder of the intestinal tube), to cure diarrhœa. Modern pathology has verified the fact, that gastro-intestinal irritation is the most fertile source of infantile diseases, and that there are few, if any infants free from it.

On examining the bowels after death, they are generally relaxed and inflated, and often inflamed, ulcerated, and their tissues softened, thinned, and easily torn with the finger. There are several intussusceptions, as many as fifty in some cases, the result of spasm. The mucous surface undergoes a variety of morbid changes, as described by Andral, Hope, Billard, and other recent writers on pathology. But in the early stage of diarrhœa there is good reason to believe that irritation of the mucous membrane is the cause of this disease, as a

cure is generally effected by medicines proper for its removal. Then, why order emetics to increase the disease? For my own part, I can see no scientific reason. I believe that opiates and demulcents are the best means to diminish irritation in diarrhœa, and that mild aperients to expel the irritating or morbid contents of the bowels are the next best remedies. The warm bath, anodyne fomentations and embrocations, are valuable adjuvants.

When the infant suffers from flatulence, and foetid or offensive motions, the treatment already described for these diseases should be employed, as the aperients recommended to induce the expulsion of the meconium, to relieve constipation, gripings, and colic. Small doses of calomel are also advisable, to improve the secretions. This medicine may be given in alterative doses, or as recommended by Dr. Joseph Clarke—half a grain rubbed up with sugar, morning and evening. This quantity may be given to an infant only a few days old, and we may order a grain for those of a few weeks or months. Dr. Cheyne thinks small and repeated doses of mercury the most effectual remedy for long continued purging at the period of weaning. I doubt much whether oils ought to be proscribed on account of their disposition to rancidity (Capuron). I have repeatedly ordered castor oil with oil of anise-seeds in this disease; and the result has been most favourable. I am ready to admit that oily or fatty medicines or foods are improper if given freely and for a continuance; but experience does not warrant me to conclude, that a dose or two of castor oil, with a few drops of oil of anise-seeds, can produce bad effects, on account of their tendency to become rancid in the bowels.

Whenever diarrhœa produces great prostration of strength or debility, it is necessary to give nutritious aliment, such as beef tea, arrow-root, sago, tapioca, and other vegetable jellies, rice, milk, toasted flour, boiled with milk, and a small quantity of white wine. If there is vomiting, these substances may be ordered in clysters, with the addition of a few drops of laudanum. Dr. Burns advises us to support the strength with the aliments just mentioned, during the whole course of the disease; but Dr. Dewees objects to the employment of beef tea, when fever is present. He has always found the vegetable jellies much safer.

It will be also advisable to attend to the diet of the nurse, or change her in some cases. Dr. Blundell informs us that sometimes diarrhœa will continue after all remedies had been fairly tried, until the infant is removed into the country, and enjoys a pure air.

After having calmed the irritation of the bowels, and caused the expulsion of offending matters, we should next improve their natural tone by mild tonics, such as rhu-

barb, preparations of iron, and the other strengtheners already advised in other bowel complaints. These are only useful after the employment of the astringents already recommended, to which may be added, extract of catechu, or tormentilla (three grains), and by narcotics, such as the syrup of diacodium (poppies), to the amount of a drachm, wine, tincture, or the sedative solution of opium, in the dose of two or three drops, or a combination of theriac and diascordium.

When there is pain excited by slight pressure on any part of the abdomen, the lower extremities drawn up, the skin hot, the mouth parched with thirst, the tongue dry, red, or glazed, and the pulse rapid, there is enteritis or inflammation, which may be situated in any part of the mucous, muscular or peritoneal coat of the intestine. The disease may terminate in resolution, ulceration, or gangrene. When it terminates in resolution, there is a gradual diminution of the symptoms, and copious evacuation of the bowels. The signs of ulceration are remission of the fever, occasional rigors or shiverings, and a purulent discharge mixed with the dejections or motions. This is a very common disease in children, and generally exists in the remittent fever which is erroneously ascribed to teething or worms, to which they are liable.

Inflammation of the bowels rarely terminates in gangrene in children, though death takes place from ulcerations and perforations in some parts of the intestinal canal, as numerous dissections have verified. Gangrene is characterized in the adult by a sudden cessation of pain when it was at the highest intensity, the patient becoming calm, tranquil, and collected; but the countenance assumes an altered appearance, a cadaverous and livid hue, when hiccup, subsultus tendinum, delirium, or convulsions precede the fatal termination. I have often astonished relatives on declaring patients in the greatest danger, in fact their cases utterly hopeless, on the sudden cessation of pain in enteritis.

The indications of treatment are to allay the inflammatory action in the bowels, and to keep them open. These indications are answered by general and local bleeding, regulated according to the age, extent, and stage of the disease; by warm bath and fomentations, by emollient drinks and clysters, with opium, and by the application of leeches to the abdomen, and about the anus. Mucilaginous drinks, as barley water, linseed infusion, gum arabic dissolved in water, or common cold or iced water may be given freely, and are much desired by children as well as adults. If vomiting is troublesome it should be allayed by the effervescent draught, with a proper quantity of opium. The late Dr. Armstrong, and Mr. Bates, most strongly recommend the free use of opium in abdominal inflammations, both by the mouth and rectum. The French apply sinapisms or blisters to the feet, legs, or thighs, and have

great dependence on leeches applied round the anus.

After the removal of leeches from the abdomen, a mustard fomentation, or warm oil of turpentine should be applied for a minute or two, to excite counter-irritation, and cold lotions may also be used with advantage. When all these means have failed, the only chance that remains is to administer mercury, and induce slight salivation, or affect the gums as speedily as possible.

When infants are affected, there is generally a gelatinous softening of some part of the intestinal tube, and the inflammation may become chronic, and continue for several days or three or four weeks. Examples of this form of the disease are daily presented to our notice by the infantile remittent fever, which sometimes continues for three or four weeks.

There is great danger of a relapse of inflammation of the bowels by the use of improper food or exposure to cold, and due attention to these should be given by medical practitioners. When diarrhœa is caused by purgative medicines, the astringents, with opium, already recommended, are to be employed. If the disease arise from the suppression of cutaneous eruptions, these should be re-induced on the skin by means of warm baths and frictions over the whole surface of the body, and also by the use of diaphoretics. This plan will be also advisable when the disease is caused by exposure to cold, which suppresses the transpiration. But in this form of diarrhœa, baths and pediluvia, the heat of a warm bed, diaphoretic and cordial drinks, will re-establish the suppleness of the skin, and remove the spasmodic contraction of the pores.

It appears to me that some practitioners are in error when they contend, that nutritious diet and moderate stimulation are injurious whenever there is reason to suspect the slightest degree of inflammation; but how often do such means save life in typhus and pulmonary affections of aged persons, though inflammatory symptoms are suspected or even apparent. When an infant is reduced in six or eight hours to the lowest prostration by watery diarrhœa, with sunken countenance and cold extremities, who could think of leeching or bleeding it? stimulation is the plan to be adopted, as will appear by the remarks on the hydrocephaloid disorder caused by diarrhœa.

Lastly, when diarrhœa is caused by the moral emotions of the mother or infant, it will be necessary to establish tranquillity of mind. I have repeatedly known children who were scolded or frightened suddenly discharge the contents of the bowels and bladder; and this fact is well known to those who have the management of infants, and superintend infant schools. Dr. Morrison mentions rather a ridiculous exemplification of this fact. "I had some time back a servant who attended me during some botanical ex-

cursions; he was a confirmed stutterer, and I had occasionally to reprimand him for his giddiness. Each lecture, however, I found acted upon him like a cathartic, and I was obliged, in my own defence, to let him blunder on in his own way." It ought never to be forgotten that the natural sensibility of infancy requires the tenderest cares and most judicious management.

Children who are subject to diarrhœa should be warmly clad, and their legs, thighs, and bodies enveloped in flannel. It is scarcely necessary to observe, that a child affected with diarrhœa or other disease in the bowels should not, through a mistaken kindness, be indulged with improper articles of diet, as fruits, raisins, &c.; nor should parents attempt to cure them, unless when medical advice cannot be obtained, by exhibiting the numerous *infallible* cures published in the newspapers, or recommended by officious nurses and other gossips. When the mouth becomes apthous or affected with thrush, the disease frequently extends along the whole intestinal canal to the anus, and the surrounding parts are often red or excoriated. They should be bathed with solutions of acetate of lead and opium, and great care observed in using clysters. If the infant is often greatly enfeebled by diarrhœa, its feet swell, and it passes less urine than usual, it is threatened with dropsy, and requires the use of diuretics, sweet spirit of nitre, acetate, hydriodate and nitrate of potass, &c.

It may also become drowsy, its face pale, eyes half closed, pupils contracted or dilated, eyelids constantly twinkling or rapidly shutting and opening, and its extremities cold and moist. This state so closely resembles hydrocephalus, that it has been termed hydrocephaloid affection (a disorder like hydrocephalus), and which requires dietetic and medicinal stimulants, as brandy, or aromatic spirit of ammonia, in arrow root, beef tea, &c., with heat to the extremities. This complaint will be more fully described hereafter.

—o—

M. VIREY ON THE GENERATION OF ANIMALS AND PLANTS.

(Continued from p. 32.)

THE instinct which female insects evince in choosing the situations most favourable for the development of their eggs and larvæ, is perhaps the most admirable in their entire history, not only on account of their inconceivable intelligence, but the zeal and attachment they shew for the conservation of their offspring. Thus we see them deposit their eggs in vegetable and animal matters in a state of putrefaction, as in cheese, bacon, and other flesh, meats, &c., as certain species of flies, beetles, &c., from which result these larvæ popularly termed worms, insects, or

maggots; in excrements, in the interior of plants, and principally in the calix of flowers, which become the seat of tumours, as the nut-gall; as on leaves and fruits, as the various butterflies, in the bark and wood of trees, in the skin and flesh of animals. Thus it is for the conservation of the species that the noblest animals become the habitation of insects and of the vilest worms, and that nature sees with the same view the spider mercilessly kill the fly which was imprudent enough to allow itself to be caught in its web, the bug sucks the blood of man, the tender infant of the affectionate and bewailing mother becomes the food of the young of the destructive eagle, the fatal poison of the serpent circulates in the veins of the lion, and he in his turn devours man. What philosophic thoughts spring from these sad considerations. The eloquent and impassioned Virey thus comments upon them. "An afflicting truth daily demonstrates to us that the human race is not more favoured by nature than any other species. In common with the rest of animals, we are exposed to the attacks and insults of a crowd of truly parasitic beings, which feed and fatten on us. Looking on this fact in a philosophical point of view, it leads to a very just conclusion—that we have formed ideas of our own superiority infinitely beyond our real condition, and beyond what is the fact.

"It is the greatest madness in a being who is gnawed by parasitical animals, whose entrails are devoured by worms, to dare pretend that all that exists was made only for him, and for his happiness. This proud master of the earth, this admirer of the heavens, the prey of a miserable insect! How can an individual so frail, a machine so near its nothingness, a being exposed to so much suffering and so many dangers, an animal subject, like all others, to the same laws of nature, how, I say, could he have thought that vast universe was created for his use? Mortal, insignificant, and feeble, who lives an hour on a heap of mud (a dung-hill), humble thyself before the author of nature, for thou art but the food for worms."

It must not be supposed that the illustrious Virey means to insinuate that man is not lord of the creation. He has only expressed the opinion of Pope, in his Essay on Man, when he designates him—

"Great lord of all things, yet the prey of all."

And again:—

"While man exclaims, 'see all things for my use:'

'See man for mine,' replies the pamper'd goose.

And just as short of reason must he fall,
Who thinks all made for one, and not for all:

All are but parts of one stupendous whole,
Whose body Nature is, and God the soul."

SECTION III. — CRUSTACEA—WORMS—MOLLUSCA.—The great analogy which exists between the crustacea, worms and mollusca, enables us to notice these species in one article. Although the function of re-production is less complicated in these than insects, it is replete with facts, which assist us in illustrating the grand and mysterious function of human generation.

The crustacea have been so called from the latin word *crustaceus*, crusty, as these animals are covered with one or more crusts, as oysters, crabs, lobsters, &c. These animals resemble insects in many particulars; but they differ from them by breathing through branchia or gills, in water.

Worms, of which the lumbrici or earth worm is an example, differ from insects, by not having articulated members.

The mollusca, of which the snail is an example, differ from insects in this, that they not only want articulated members, but have regular respiratory organs, divided into spaces. In fine, zoophytes, crustacea, worms, and mollusca, are distinguished from reptiles, fishes, birds, and mammiferæ, in this, that they are deprived of a spine or vertebral column, and are called invertebrated animals. These general observations having been premised, let us now pass to the function of generation in these animals.

Crustacea.—The crustacea are of two sexes, male and female, like insects, and cannot reproduce unless by copulation, and cannot propagate except by eggs. As crabs and lobsters are the most perfect of the crustacea, the history of their generation will, with few exceptions, explain the procreation of all other crustacea.

These enjoy the singular power of reproducing their limbs, when these are separated by accident or violence from their bodies. Thus, the Spaniards cut off their limbs, and throw the dismembered animals into the water, as they know that new ones will be reproduced in a short time. Lobsters acquire a new shell every year, in the month of May, and this becomes perfectly hard in a few days. The female, as in insects, is longer than the male, and both are endowed with a double genital apparatus. The male organs are situated on the thigh of the last pair of claws.

The female has two ovaries like insects, each having a canal (style, pistil, in plants, vagina in animals), which penetrates the middle part of the thigh in two round openings, into which the male places the spermatic fluid, and through which the fecundated eggs escape. The females of the crab have longer tails than the male. Lobsters and crabs copulate in November, December, January, and February, and sometimes, though very rarely, in March.

The eggs of these animals possess the power of transforming themselves into living beings, even when they have been a

long time separated from the body of the mother, and even when they have been dried, by replacing them in water. The crustacea, though warmer than insects, celebrate their amours with greater ardour—a fact attested by fishermen, who have frequently remarked the facility with which they were caught, as regardless of all danger while engaged in the act of generation. It is worthy of remark that the males of the crustacea have two secretory organs for the supply of spermatic fluid (testicles, anthers), and the females two ovaries for the same purpose.

Worms.—The generation of these animals is still very obscure. All these are hermaphrodites; the male and female organs are united and placed in the middle of the body. Nevertheless, they cannot engender without sexual intercourse; but this consists in frictions of the generative organs, and not in intromission. They deposit their eggs on the surface of the earth, where they develope like those of insects.

It has been stated, that the crustacea possess the remarkable faculty of reproducing their limbs (claws) a number of times. But worms possess a power still more remarkable, for if cut into a great number of parts, each of these transforms itself into a perfect worm (lumbricus). These possess both classes of sexual organs, and are not required to generate as other species. We shall observe hereafter, that in man and other animals, irritations of the skin produce perfectly similar sympathetic effects on the generative organs.

Mollusca.—These may be divided into three orders, as regards their reproductive functions.

1. There are some hermaphrodites, as in worms, which cannot propagate without the aid of another individual: such as snails and all the order of gastropedes or those that walk or crawl on the belly. The sexual organs in snails are placed on the right side of the neck. It is by the opening in this part that the excrements of the animal are also expelled, that the eggs pass or are laid, which are deposited on the earth like those of worms.

2. There is another species which have the sexes different, that couple and reproduce like insects. Among these are the cuttle-fish, flying-fish, &c., which are termed *cephalopodes*, from moving with the head forwards.

3. There are mollusca which are perfect hermaphrodites, and can propagate without any copulation—oysters, muscles, &c., those denominated *acephalores*.

We shall see hereafter that there are even some acephalous mammiferæ, that propagate, though entirely deprived of heads.

Thus we observe that perfect hermaphroditism does not exist except among the lowest and feeblest animals, such as are not in a condition to search for an object fitted for reproduction. But this condition is never observed among insects, reptiles, fishes, birds, or the mammiferæ, including the human species, living beings endowed with great in-

nervation or nervous sensibility, and great locomotion and power of action, and always in a condition to make active search for the object which leads to reproduction. Thus we see the great precaution and wisdom of nature in not uniting the two sexes (which indeed would be physiologically impossible) in individuals of a vivid sensibility, which would enjoy every moment of their existence, the means of pleasure and of destruction. There never was a perfect human hermaphrodite, as such a being could not possibly procreate within itself, and would be contrary to the laws of nature.

SECTION IV.—FISHES.—Fishes are generally oviparous; they secrete and deposit their eggs. The females possess ovaries like insects, &c. Some possess the sexual organs separate. These organs are placed on the abdomen, near the tail, which also permit the evacuation of excrementitious matters. It is through this aperture that the male introduces the spermatic fluid, which is denominated the roe or milt. There are some fishes, as the cartilaginous, which copulate like mammiferous animals, and others that deposit the eggs outside the body; and these are impregnated by the addition of the seed of the male. It is even proved that the eggs of some fishes, after being dried, remain fecund when immersed in water; and that those of the pike may be swallowed by birds, be unaltered by their gastric fluid, and after being expelled, still retain the faculty of being transformed into living beings. The fecundity of fishes is perfectly astonishing, some of them containing from one to six hundred thousand eggs. This fact will be fully illustrated in the chapter on fecundity. It shews that nature, ever careful of her children, enables fishes to withstand the wars of insects, crustacea, birds, and even man, by their great fecundity. It is also a remarkable fact, that if fishes be deprived of the male and female organs of generation, and they have been subjected to castration, that in a short time afterwards, their flesh becomes infinitely more delicate and tender. The same fact is observed in plants, birds, and mammiferæ, and even the human constitution is very much changed by castration.

Thus, in proportion as we advance in the study of the generation of animals, we acquire the most striking proofs that all living beings are governed by the same laws, that life is the same in all animated nature, that the phenomena of existence do not differ but by the presence, absence, perfection or defects of certain organs; and that man does not differ essentially from the parasitic insect which he crushes and kills without pity, which, however vile he may suppose, has nevertheless no less incontestible right to nourish itself with his blood, or on the morbid fluids on the external or internal surface of his body, than he has to eat the flesh of the innocent lamb, or the wren which he destroys

with the fatal lead, while performing its delightful maternal cares.

Reviews.

A New Practical Formulary of Hospitals of England, Scotland, Ireland, France, Germany, Italy, Spain, Portugal, Sweden, Russia, and America; of MM. Magendie, Lugol, Dupuytren, Alibert, &c. &c.; or a Conspectus of Prescriptions in Medicine, Surgery, and Obstetrics. With the Doses of all new and ordinary Medicines. Translated from the New French Edition of MM. Milne Edwards and P. Vavasour, and considerably augmented. By Michael Ryan, M.D. Member of the Royal College of Physicians in London, &c. Royal 32mo. pp. 572. London: Henderson. 1835.

WE do not intend to review this work farther than insert the translator's preface. The work has already received the most extensive encouragement, and a large portion of the edition is disposed of already.

"This little work is the production of two eminent physicians, Dr. Milne Edwards and Dr. Vavasour. It is a *conspectus* of the best prescriptions of the most celebrated physicians and surgeons in the practice of medicine, surgery, and obstetrics throughout the civilized world. It is a modern UNIVERSAL PHARMACOPEIA, and contains a vast number of new remedies, seldom, if ever, employed in this country, as well as many thousand medicines that have been omitted in our Pharmacopœias. The doses and uses of all are given. It includes every medicine described in the British Pharmacopœias, and in the eighth edition of the celebrated Formulary of M. Magendie, published in March, 1835.

"It possesses other important features unnoticed in our works on *Materia Medica*, with the exceptions of those of Dr. Paris and Dr. A. T. Thomson. These are the rules for prescribing; the explanations of the actions of medicines on the economy; the various modes of administering them; the principles on which they are compounded, for the attainment of the various objects desired; and, lastly, their division into official and magistral or extemporaneous prescriptions.

"It is scarcely necessary to observe, that the multifarious and almost illimitable objects which occupy the mind in the study and practice of medicine, require that the memory should be frequently refreshed, and reference made to the doses, uses, and administration of remedies. A Pocket Remembrancer is therefore indispensably necessary, and this work is the most comprehensive and best hitherto published in this country. It is, in my opinion, infinitely superior to, and more useful than, any other

conspectus of the pharmacopœias, or of prescriptions, in our language. It contains far more important and modern information. The objects of its authors were to unite, in a commodious and portable form, the most efficacious formulæ, and to offer to students and practitioners a chart in which they will find, with facility, the best remedial means. It cannot be expected to find all the prescriptions hitherto published, but choice examples which fulfil the principal objects in therapeutics. The work has been most favourably received in foreign countries, and cannot fail to obtain as great popularity in this kingdom.

"The translation of this work from French into Latin and English, was a troublesome undertaking. The names of many thousand medicines, seldom employed in this country, were given in popular French, and were to be rendered strictly scientific. To effect this, much research was necessary, and a vast deal of reference inevitable, which might have been avoided, were the scientific names given in the original text. It was, however, considered right to give a literal translation in English and Latin. This will account for the simplicity of the directions, as to the doses and modes of administration of medicines. It is also to be recollected that many of the prescriptions were intended for hospital, and not for private practice; and hence, as many as a hundred or more pills, for example, are ordered in one prescription. It is not difficult to proportion the number for private practice; and I make the observation, as many practitioners have requested me to do this in the present form of the work. I need scarcely remark, that were I to comply, I could not be considered a translator, but a condenser of the original text.

"I have verified many of the original statements in my own practice, and placed all my additions in parentheses, so as to distinguish them from the original. I deemed this necessary, because some, perhaps many, would be disposed to doubt the efficacy of some of the formulæ, unless they are attested by a British practitioner. My statements can be confirmed by many intelligent and observant students. I may also add, that Dr. Bardsley, of the Manchester Infirmary, has, in his admirable clinical reports, proved the efficacy of most of the new remedies hereafter mentioned.

"It is to be hoped, that the framers of the London and Edinburgh pharmacopœias, who are now engaged in revising their works, will take a hint from passing events, and no longer leave their codes half a century behind the present state of science. It is but justice to state, that the Dublin Pharmacopœia is far superior to either; but it has been published later.

"Those engaged in actual practice care little about this or that pharmacopœia; they ardently wish to obtain a knowledge of ef-

ficacious remedies, from whatever source. They adopt the Celsian axiom—"Morbos, non eloquentiâ, sed remediis curarii." The Colleges may amuse themselves with Greek and Latin, but these languages, however delightful, will not cure diseases.

"In fine, this little book is calculated to effect much good. It is presented to British practitioners, though augmented and increased in size by the translator, at nearly the same expense as the French edition; and is much cheaper than any other conspectus in the English language. This is only a slight recommendation in its favour; but, when the work is known, it cannot fail to be encouraged."

A Treatise on Pulmonary Consumption: comprehending an Inquiry into the Causes, Nature, Prevention, and Treatment of Tuberculous and Scrofulous Diseases in general. By James Clark, M.D. F.R.S. Svo. pp. 399. London: Sherwood & Co.

(Continued from page 21.)

CHAP. 3 treats of the *particular symptoms and signs of consumption*. Our author observes, with truth, that the symptoms of consumption vary greatly in different cases, and that there is scarcely one even of the leading symptoms which may not occasionally be absent. It has been asserted that tuberculous disease has in some instances proved fatal almost without any local symptoms.

"This, however," says Dr. Clarke, "is by no means in accordance with my own experience; certainly I have never met with such a case, nor can I easily believe that tuberculous disease of the lungs should run its course without affording sufficient indications of its existence. If cough and expectoration be wanting, we shall find hurried breathing; and if regular hectic be absent, there will still be the rapid pulse, or the frequent chills, the night perspiration, or diarrhoea, and emaciation: more or fewer of these symptoms are always present, and, together with the peculiar cachectic character of the countenance, enable us to detect the real nature and seat of the disease. There will at least be found enough, I believe, in the most obscure cases, to excite the suspicions of the observing practitioner; and when these are once aroused, the *physical signs*, which diseases of the lungs always afford, will soon satisfy him respecting the real nature of the malady."

These remarks we believe to be perfectly just. The fact is, doctors, like other people, are fond of the marvellous, and many would fain add an appendix of *morbi prodigiosi* to

the systems of nosology; to this class all diseases which have no symptoms ought unquestionably to be referred: all we can say upon the subject is, that we never meet with any such maladies; we often encounter symptoms without being able to detect the morbid states on which they depend; but we have never yet been confronted with a morbid state of any important organ, which was not indicated by symptoms of *some kind or other*.

Under the head of particular symptoms of phthisis our author treats of cough—dyspnoea—expectoration—hemoptysis—pain of chest—the pulse— hectic fever—perspiration—thirst—diarrhoea—emaciation—œdema—aphthæ. The following remarks on *gastric and abdominal cough* are highly worthy of attention:—

“*Gastric cough*.—The cough which is next in importance, in a diagnostic point of view, is that which has not inaptly been termed the *stomach cough*. Gastric irritation is frequently attended with cough, not unlike that which accompanies the early stage of tuberculous disease. A little attention, however, will enable us to discriminate them. In general, the cough which attends gastric irritation is louder and harder than the phthisical, and frequently comes on in paroxysms: the source of irritation is felt deep in the epigastric region; and the irritated state of the stomach is generally rendered manifest by other symptoms. The tongue is red at the point and edges, generally furred in the centre, and often dry on waking in the morning; there are thirst, some quickness and a contracted state of the pulse; the extremities are cold during the day, and a preternatural heat of the hands and feet often prevails during the night; the bowels are generally costive, and the urine is high-coloured. These symptoms are frequently accompanied by frontal headache, especially in the evening, and by an irritability of temper unusual in the patient. If he is accustomed to mental occupations, he finds himself less disposed and less able to exert his mind. The expression of his countenance also changes remarkably—he becomes pale and sallow, and his features are fallen: he has the look of ill-health; he feels unwell, and yet, on being questioned, he cannot fix upon any local complaint. This state often continues for a long period, and in many cases without much loss of appetite—a circumstance which tends to deceive the patient respecting the seat and nature of the malady.

“An attentive investigation will generally satisfy us that the disease is seated in the digestive organs, and we shall find that the cough and other symptoms will gradually yield to proper treatment, and the health will

be frequently restored in a very short time, especially if the patient is young. A gentle antiphlogistic treatment, and a strict adherence to a mild diet, will soon show the nature of the disease, by the marked and speedy relief which they afford; and, in truth, will be at once the best test of the accuracy of our diagnosis and the soundness of our pathological views as to the cause of the cough. Even when gastric irritation is complicated with incipient consumption (a very frequent occurrence), our treatment must be directed in the first instance to the cure of the former, as the surest means of enabling us to arrive at a correct knowledge of the patient's condition.

“There is another form of cough which properly belongs to the stomach, as it originates in, and is kept up by, a deranged state of that organ. This cough occurs later in life. It is accompanied by a considerable expectoration of tenacious mucus, which, from its occurring chiefly in the morning, has received the name of ‘morning phlegm.’ It is generally the consequence of too free living, and accompanies the last ten or fifteen years of the gourmand's life: it is easily distinguishable from the tuberculous cough.

“Both these stomach coughs deserve attention, not only on their own account, but more especially when they occur in a tuberculous constitution. The first form of the gastric irritation, when of long duration, greatly favours the formation of the tuberculous diathesis; and may thus prove fatal from its nature being mistaken and its treatment misdirected. The second occasionally masks tuberculous disease, occurring at a more advanced period of life.

“*Abdominal Cough*.—Irritation of the liver and duodenum, intestinal worms, and irritation of the uterus, often give rise to cough. The cough which is present in chlorotic patients, and which is probably dependent on functional derangement of the uterus, may in general be easily distinguished from the phthisical cough, by the other symptoms with which it is associated, and by the facility with which it yields to a mode of treatment which would have little effect in relieving the latter. It must be kept in mind, however, that young females of a tuberculous constitution are the persons most liable to chlorosis, and on this account their cough must not be treated too lightly, nor a prognosis given without circumspection.”

We may further observe, that the cough arising from irritation of the liver is frequently attended with profuse nocturnal sweats, dependent on the same cause; they differ, however, from those of phthisis in not being preceded by any marked febrile stage. We have frequently found these perspirations to disappear almost immediately on the administration of

the blue pill, especially in the minute doses recommended by Dr. Wilson Philip.

On *dyspnœa*, Dr. Clark comments as follows :—

“ This symptom, although never wanting, varies greatly in the degree of its intensity in different cases. In some instances it occurs early in the disease, being among the first circumstances which attract the patient's attention; and it is one of the most constant and remarkable symptoms in the *febrile* form of the disease. When the tuberculous disease makes slow progress, *dyspnœa* is little felt; and in persons who, from their quiet mode of living, use little exercise, it is scarcely noticed even when the frequency of the respiration is nearly doubled. In such cases the oppression in breathing experienced during exertion is very often attributed to debility. Indeed it is by no means uncommon to find the patient unwilling to admit the existence of *dyspnœa* until minutely questioned. Consumptive patients are often jealous of being interrogated respecting any symptom connected with pulmonary disease; and then occasionally conceal symptoms from the physician, who, if he desires to arrive at the truth, must put his questions with great caution, and without appearing to attach importance to them.

“ We shall not, I believe, err far in stating that the degree of *dyspnœa* or hurried respiration (for I class both under the same head) will generally be found proportionate to the extent of the tuberculous disease of the lungs and to the rapidity of its progress. Of a hundred and twenty-three cases reported by M. Louis, three only presented examples of severe *dyspnœa*; and a careful examination of the whole contents of the thorax after death, detected nothing by which to explain it. Congestion of the lungs frequently occurs in persons of a tuberculous constitution, both before and after the formation of tubercles, and may be one cause of *dyspnœa*; and hence we frequently find that an attack of hemoptysis, or venesection, employed to subdue it, relieves both the cough and *dyspnœa* for a considerable time. On the other hand, it not unfrequently happens that the origin of the difficult breathing is dated from an attack of hemoptysis: I have frequently observed this, but am unable to account for it. I here allude to the protracted *dyspnœa*; that which immediately succeeds the attack of hemoptysis most probably depends upon the effusion of blood into the pulmonary tissue, and the consequent compression and obliteration of the air cells to a greater or less extent. We are not yet acquainted with all the causes of *dyspnœa*; one is often to be found in a feeble heart, which, by being easily oppressed, gives rise to it.

“ *Dyspnœa*, therefore, although not much to be relied on as an indication of the very

early stage of consumption, should always be a subject of inquiry; and it will be found, I imagine, more frequently present than is generally believed. It is experienced chiefly during exertion, and as it differs little for some time from the oppression which in a slight degree always accompanies exertion, it seldom attracts attention. Being slow and gradual in its increase, and, like many other morbid states, unattended with pain, it is little noticed until it has become very considerable. But as tuberculous disease of the lungs cannot exist to any extent without more or less *dyspnœa*, the presence of this symptom together with emaciation should induce us to examine the chest with care, even were there no other indications by which consumption might be suspected.”

The practitioner should always judge of the existence and degree of *dyspnœa* from his own observation rather than from the account given by the patient; since persons labouring under phthisis will often declare that they have no difficulty of breathing, when the increased play of the nostril, excited by the smallest exertion, too plainly indicates the contrary.

There is a fact connected with the state of the respiration in phthisis, to account for which might puzzle the physiologist; it is this: in some cases, when the disease is within a few hours of its fatal termination, after the patient has been long harassed by extreme *dyspnœa*, all *consciousness* of difficulty of breathing suddenly ceases, although the respiratory muscles continue in a state of increased action. It might be supposed that the absence of uneasy sensation arose from diminished activity of the circulation; but we have observed it where the heart was acting with great violence, and the pulse was exceedingly full and frequent, as often happens till within a very short time before death. It may possibly be referable to diminished energy of the brain, in consequence of which the uneasy sensation arising from deficient arterialization of the blood is not perceived; and this we think is the most probable solution; it is indeed true, that the phenomenon in question is sometimes observed where the intellectual powers remain, to the last moment of life, in a state of perfect integrity, or even of high exaltation; but we are of that old-fashioned school of physiologists who believe that the *soul* is one thing, and the *brain* another; and hence, that a man may retain a perfect capacity of thought

at a time when *sensation* has become obscured or almost extinct.

The subject of *expectoration* is one to which more importance was attached formerly than the present state of morbid anatomy can concede to it.

"Pus, which was so carefully looked for, and to recognise which so many experiments were made, is now well known to be present when only bronchial disease exists; it does not therefore form an essential character of tuberculous expectoration. But although no physician of the present day would think of relying on the expectorated matter as a test of the nature of the pulmonary affection, still a knowledge of the characters exclusively belonging to the expectoration which accompanies tuberculous disease is interesting. The transparent, frothy, tenacious sputum, though it often indicates the presence of tubercles, is evidently a secretion from the bronchial membrane, and may occur independently of any tuberculous disease. The same may be said of the yellowish-green expectoration, which is often discharged in large quantities in chronic catarrh, and towards the termination of bronchitis; and there is no doubt that the greater part of the expectoration in tuberculous diseases of the lungs is derived from the same source.

"There are two characters, however, which may be considered peculiar to the expectoration attending tuberculous disease: the striated state of the expectorated mass, with a mixture of whitish fragments in it, and the ash-coloured globular masses, which are observed in the more advanced stage of the disease. I have never seen this last form unaccompanied by tuberculous disease; but it has been observed by Chomel and Louis in two cases during the last days of life, where neither tubercles nor tuberculous excavations, nor dilated bronchi were detected after death. The very circumstance, however, of its having been found only in two cases, by such accurate observers, shows how very generally it is connected with tuberculous disease. The different characters of the expectoration already noticed present themselves, for the most part, as has been before stated, in the course of pulmonary consumption. They occurred in all the cases described by Louis, with three exceptions, in which the ash-coloured masses never appeared, the expectoration continuing semi-transparent, or of a slightly yellowish hue, to the last."

The cases in which expectoration is entirely absent throughout the course of the disease are extremely rare; Dr. Clark has met with only one instance of this kind.

"I have only met with one decided case in which the absence of expectoration continued to the last;—on examination, the lungs on

ne side were found converted almost entirely into a mass of tuberculous disease, containing numerous small tuberculous vomices, and one of considerable size: the upper part of the other lung was also tuberculous, and some of the tubercles were softened. The cough in this case was so slight as scarcely to be remarked; but the rapid pulse, the quick breathing, the night-sweats, and emaciation were more than sufficient to indicate the nature of the disease, independently of auscultation, which left no doubt on the mind:—there were, however, circumstances in the case, which, without the assistance of auscultation, would have thrown a shade of obscurity on its nature. In other instances, large excavations are found communicating freely with the bronchi, although, for a considerable period before death, neither cough nor expectoration was present."

Under the head of *physical signs* some judicious observations on the employment of auscultation will be found.

CHAP. 4, on the *Morbid Anatomy of Tuberculous Disease*, contains a judicious abstract of all that is known upon the subject, which, however, has been so amply illustrated by recent and well known authors, that it is unnecessary to enter upon it here.

CHAP. 5 is on the *Cure of Tuberculous Disease of the Lungs*.

"That pulmonary consumption admits of a cure," says our author, "is no longer a matter of doubt; it has been clearly demonstrated by the researches of Laennec and other modern pathologists. 'Pathological anatomy,' says Dr. Carswell, 'has perhaps never afforded more conclusive evidence in proof of the curability of a disease than it has in that of tubercular phthisis.'"

It would perhaps be more correct to say, that where the tuberculous diathesis exists, and has been called into *partial* activity in a limited portion of the lungs, the tuberculous matter may be expelled, and the cavity which it occupied, obliterated.

These however are comparatively rare cases, and the general incurability of pulmonary consumption is a fact attested by melancholy but universal experience.

"In recording these proofs of the curability of pulmonary tubercles, I think it right to remark that I do not attach much importance to them, further than that they afford encouragement to persevere in our endeavours to correct the tuberculous diathesis; seeing that nature can remedy the local disease when it is not very extensive. We must never allow our hopes of such a termination of the disease, nor our endeavours to promote it by local remedies, to divert our attention from

the constitutional treatment. Unless we can correct the constitutional disorder in which local tuberculous disease has its origin, such cure is of little avail, as it is usually succeeded by fresh deposits of tubercles to an extent which renders recovery hopeless. It not unfrequently happens that young persons are attacked with symptoms of phthisis, which, under proper treatment, cease, and years elapse before there is any renewal of the disease. Were advantage taken of the intervening period to correct the tuberculous diathesis, the cure might prove perfect. I have known recoveries from two such attacks, the third proving fatal; the interval between the first and last attack was twelve years.

"The opinion of Laennec on this subject is so important, that I shall cite his words: 'We may indeed say, that the greater number of cases of phthisis are latent at the beginning, since we have seen that nothing is more common than to find numerous milary tubercles in lungs otherwise quite healthy, and in subjects who had never shown symptoms of consumption. On the other hand, from considering the great number of phthisical and other subjects in whom cicatrices are found in the summit of the lungs, I think it is more than probable that hardly any person is carried off by a first attack of phthisis. Since I was first led to adopt this opinion on anatomical grounds, it has frequently appeared quite clear to me, from carefully comparing the history of my patients with the appearances on dissection, that the greater number of those first attacks are mistaken for slight colds, and that others are quite latent, being unaccompanied with either cough or expectoration, or indeed with any symptoms sufficient to impress the memory of the patients themselves.' I am satisfied, from my own observation, that Laennec's opinion is correct. Tuberculous disease of the lungs in early life is, I believe, frequently cured; but it very generally recurs, often at an advanced age, and ultimately proves fatal. The cases of this kind which I have observed have been most frequently in females. While proper measures, therefore, are adopted to abate pulmonary irritation and congestion, our utmost endeavours should be directed to correct the constitutional disorder, as the only sure means of obviating a renewal of tuberculous disease."

(To be continued.)

—o—

LUNATIC ASYLUMS.

To the Editor of the *London Medical and Surgical Journal*.

SIR—The letters of Democritus and Philodemocritus, which have appeared in your *Journal*, the former in the number for Feb. 14th, and the latter in the number for July 11th, of this year, although dictated appar-

ently by the best motives, contain statements which I believe are exaggerated, and propositions which, if acted upon, will certainly do much more injury than benefit to the cause they are intended to advocate. Before, however, I proceed to make any remarks on the letters in question, I wish frankly to state that I am personally interested in the subject to which they refer. My father, Mr. Thos. Bakewell, has kept a private establishment for the reception and cure of lunatics since 1808, and I have been educated with the view of succeeding him in the management of it. At present I am residing with him, and assisting him. Allow me also to express my satisfaction that the subject of the treatment of the insane has attracted your attention, and to assure you I hail with satisfaction the present discussion, hoping that it will be conducted in a candid spirit, and that equal justice will be dealt out to all parties.

It is, Sir, my sincere conviction that instances of rapacity and insensibility on the part of the friends of the insane, are really not so numerous as the representations contained in the letter to Sir R. Peel would lead us to suppose, and that the author of it has painted his picture in rather too dark colours. That circumstances of the character he mentions have occurred in times now happily gone by, there is too abundant evidence in the Reports of the Committee on Mad-houses, which sat in 1815 and 1816, to allow us for a moment to doubt; but I must also express my belief, that since that time great improvement has taken place, and that in no one thing has greater progress been made of late than in the treatment of the insane, in point of both humanity and skill. I think it therefore ungenerous and ill-advised to treat those who employ themselves in the care and cure of the insane in the suspicious and discouraging manner in which it is now so much the fashion to treat them. The severe restrictions and oppressive enactments which have been passed within these few last years might have been justified immediately after the discovery of the horrid abuses which did undoubtedly exist in some asylums (public as well as private); but I contend that they are now uncalled for, and that so great a change for the better has now taken place, that all concerned in this department of practice, especially those who were never guilty of such malpractices, deserve encouragement instead of the odium which is so unjustly heaped upon them.

Whatever abuses may have become known to the writer of the letter to Sir R. Peel, I beg to say, that there are several private establishments to which his animadversions will not apply. I will venture to assert further, that private establishments have been as free from abuse as public ones. If you will refer to the Report on Mad-houses, you will find that instances

of neglect, and of insufficient accommodation, were discovered in public as well as in private institutions. I know, Sir, that there are many others of the same opinion as your contributor—that many, and among them some medical men, think that county asylums would prove a panacea for all the evils attendant on the management of the insane, and that, in fact, all the private asylums should be put down by law. But I beg of such persons to pause awhile, and to examine more minutely into the subject, before they come to such rash and unwise conclusions. Let them look at the comparative success which has attended the treatment pursued in public and private asylums, and they will find, perhaps to their surprise, that the latter bear off the palm. I beg to refer them to a table inserted in Dr. Burrows' "Commentaries on Insanity;" the table in question was published in 1820, and its correctness has never been impugned. It should be premised that the majority of cases received into public institutions being paupers, are most of them of more recent date than those received into private asylums, because the overseers of their respective parishes have no motive for keeping them, and are glad to get rid of them as soon as possible. With even this advantage, it will be found that the highest proportion of cures of which they can boast is as follows:—

	Recent cases.	Old cases.
Glasgow .	50 out of 100	— 13 out of 100
York . .	45 — 100	— 12 — 100

These are the only public establishments in which a distinction is made between recent and old cases, and therefore the only two with which a correct comparison can be made.

The returns of the private asylums are as follows:

	Recent cases.
Laverstork (Dr. Finch's) .	71 out of 100
Droitwich (Mr. Rickett's) .	76 — 100
Spring Vale (Mr. Bakewell's)	84 — 100

	Old cases.
Droitwich (Mr. Rickett's) .	17 out of 100
Spring Vale (Mr. Bakewell's)	35 — 100

Dr. Burrows says that his proportion of cures is 91 out of 100 of the recent cases: the Retreat has a proportion of 86 out of 100 of the recent, and 35 out of 100 of the old cases. It is placed in the list of public asylums, but partakes more of the character of a private one—it is not a *county* asylum.

We have equally the advantage with regard to the health of the patients, and the smaller proportion of deaths. The returns of the Wakefield County Asylum, which is said to be the best in the kingdom, show a proportion of 24 deaths in 100 of the whole number of cases admitted in nine years. The Lancaster Asylum, 24½ in 100 in twelve years; and the Stafford Asylum, 16 in 100 in sixteen years; while the proportion at Spring Vale, since 1808, and in Clapham Re-

treat (Dr. Burrows'), has been not quite 7 in 100. I do not wish, however, in drawing these comparisons, to display a hostile feeling towards county asylums. I merely wish to show that they have no claim to the support and patronage of the public superior to that of private establishments. Confined to their proper sphere, and conducted on different principles to those on which they are at present conducted, they might be the means of doing much good, and should receive my humble support; but they have no right to encroach on the privileges of private practitioners, and to usurp that place, in the estimation of the public, to which they have no lawful claim, and to which private establishments have much greater pretensions. They are in fact by no means the efficient and valuable institutions they are represented to be. They are most of them too large, and, by receiving all classes of patients, contain too many inmates. Stafford, at the time of the last report, contained 201, and Hanwell contains 500! Now, sir, however excellent the design of the building and the internal arrangements may be, so great a number of patients cannot have that free range into the neighbouring country, which conduces more than any other moral means to their recovery, and the building containing them must have more the aspect of a prison than an agreeable residence.

There is another subject on which I am anxious to say a few words. Your contributor, Democritus, says, that "the certificate of a single medical man should not, *as at present*, justify protracted confinement in a madhouse, or being sent to one. Before a step of such paramount importance is concluded, a solemn inquiry should be instituted, and that inquiry should consist of three or five, with powers to decide the question of sanity or insanity; and when insane, whether the individuals so found should be sent to a mad-house, or treated privately." These remarks would lead me to infer that the writer knows nothing of the matter he has written about. It so happens, in the first place, that *two* certificates are now required by the law; and, in the second place, he ought to know, that when the question of insanity is decided in the affirmative, there can be little further doubt as to the propriety of removing the patient from home. Whether the patient shall be removed to private lodgings, or to an establishment, is a question for the friends of the patient to decide, as it is generally one of economy. From the expense attending the proper treatment of lunatics in private lodgings, and the difficulty of procuring suitable servants to take care of them, a private establishment affords, for persons in moderate circumstances, by far the most desirable resource, as regards economy and the means of safety and recovery. But, with regard to the necessity of an inquiry

by three or five persons before a lunatic can be removed from home, the following considerations are worthy of notice:—In the majority of instances, the existence of insanity is evident enough, and cannot require the verdict of three or five persons to remove doubt on the subject; and the fact of insanity existing being clearly ascertained, no time should be lost in placing the patient in the situation most likely to secure his recovery. Now, the holding the solemn inquiry would in itself cause hurtful delay; and, what is worse, would necessarily be attended with so much publicity that many would be deterred from submitting to it, and would, therefore, keep their afflicted friends at home (the worst place in the world for them), until the malady had become so developed as to render the patient's society intolerable, when it would very probably have become incurable. Instead of difficulties like these being thrown in the way of the early removal of the patient from home, every facility should be afforded; care, however, being taken, that the receptacles for the insane be suited to their purpose, and properly conducted. This might be done by other means than the suspicious system now pursued, and recommended to be carried to a still greater extent by your last correspondent, Philo-Democritus. One plan recommended by Dr. Burrows, and, in my opinion, a very good one, is to allow none but medical men to conduct establishments professing to cure insanity, and, of course, allowing recent cases to be placed in none but such establishments. This plan would tend, certainly, to render private houses more respectable, to increase the confidence of the public in them, and consequently to afford greater facilities to the afflicted in procuring a remedy for their complaint.

I would willingly join in the eulogium passed upon Lord Robert Seymour, at the conclusion of the letter. That he is kind-hearted and benevolent, I readily allow; but it may well be questioned, whether it is "devoutly to be hoped that his views may be carried into effect." They are much the same as those of Robert Gordon, Esq., who brought forward a Bill, which is now the law of the land, to regulate the care and treatment of insane persons in England and Wales. In reference to this Bill, Dr. Burrows makes the following severe but just remarks:—

"Certainly," says he, "no measure introduced into Parliament ever betrayed greater want of information, and consequent misconception of a subject;" and again, "If any thing is to be feared that may check the progress of improving the treatment, moral and medical, of the insane, it is these absurd attempts to effect it by legislation. The inevitable consequence is, to disgust honourable and well-educated men, and to deter them from pursuing a branch of the

medical art, in the exercise of which they cannot be free agents, and which degrades them and marks them as unworthy of public confidence." I have only to observe, that I fully concur in these sentiments, and remain, Sir,

Your obedient servant,

SAMUEL G. BAKEWELL, M.D.
Spring Vale, near Stone, Staffordshire,
July 29th, 1835.

Foreign Medicine.

Objection to the generally received Doctrine of Animal Heat.

THE theory of animal heat leads to the conclusion that the elevation of temperature should accompany the greatest activity of respiration. M. Donne, however, in a paper read before the Société Philomathique, May 1835, remarks that observation proves that the maxima of temperature takes place when sanguification is very deficient. In phthisis, the temperature, instead of being 36 deg. as in the healthy condition, is raised to 40 deg., though the lungs are at the time almost totally destroyed, and the pulse does not exceed eighty-four beats in the minute.

Treatment of Itch.

From numerous experiments made by M. Emery, at the Hôpital St. Louis, the following formula, the base of which is taken from Hafenreffer, used in friction, night and morning, cures the itch in less than a week. Of twelve hundred individuals thus treated, very many were cured in four or five days, others only in ten, twelve in fourteen days. The preparation does not dirty the linen, has no bad odour and is cheap.

Yellow soap	1 oz.
Sea salt	$\frac{1}{2}$ oz.
Sulphur	$\frac{1}{2}$ oz.
Alcohol	1 dram.
Vinegar	2 drams.
Choride of calcium . . .	$\frac{1}{2}$ mix.

This quantity suffices for four frictions.
—*Bull. de Therapeutique.*

Caustic of Chloride of Gold for Cancerous Affections.

M. Recamier has lately been using this preparation in several cases of cancerous affection of the face and cervix uteri. He was led to the use of it by observing a jeweller who had a cancerous fungus on the cheek, which induced him frequently to apply his hand to it at the time when he was employed in forming a solution of gold in aqua regia; the fungus disappeared. M. Recamier paints the surface of the carcinoma as in cauterizing with nitric acid and other liquid caustics. It is made by combining one ounce of nitro-chloric acid with six grains of pure chloride of gold, by which an

aqua regia is obtained with an excess of chloric acid.

The effects are rapid; two applications generally produce marked effects on the cancerous tissue; in one patient that was entirely cured by this means, eight applications sufficed—*Bull. de Therapeutique*.

Constipation—Faces extracted by the Fingers.

A case of this kind is related in the *Gazette des Hopiteaux* of June 1830; it occurred in a lady, and a midwife performed the operation.

This is one of the consequences of the filthy habit so common among French females of resisting the calls of nature, and allowing an accumulation to go on in the bowels until the abdomen is actually visibly enlarged thereby. Any medical man who has resided in Paris a few months, will not have failed to make the same observation.

The London Medical

AND

Surgical Journal.

Saturday, August 8th, 1835.

INSUFFICIENT REMUNERATION OF MEDICAL PRACTITIONERS.

WHEN the House of Commons was last week in committee on the County Coroner's Bill, Mr. Wakley represented in a forcible manner, the injustice of expecting medical men to perform dissections relating to legal inquiries, without adequate remuneration. Such dissections are often insufferably disgusting to the senses, even of those who are accustomed to anatomical pursuits—they are attended with considerable personal risk to the operator—they frequently consume much time, and always demand the most careful exercise of a practised judgment: add to all this, that the practitioner who conducts such an investigation is to draw from it an opinion whose accuracy involves his own reputation for professional knowledge and sagacity, and it will at once appear evident that he is entitled to the highest remuneration that the state can afford to give him. It is necessary to dwell on such points, because there unfortunately exists in the British public,

an extreme disinclination to recompense medical men for the numerous sacrifices of time, convenience, and health, which they, more than any other class, are expected to make for the good of the community; the profession is respected—deferred to—made much of—everything but *paid*. If, however, the public be wanting in liberality towards the profession, it must be confessed that the latter have in some measure been the cause of this, by an injudicious readiness to give their services *gratis*, or a dishonest pretence at doing so, when they are in reality well paid; thus the physician to a large dispensary undertakes gratuitously a duty which, if *properly fulfilled*, will occupy his whole time and attention, and demand a degree of bodily and mental labour, to which very few men will find the strength of their constitution equal; yet a great many meritorious young physicians toil for years in this unproductive field, ruining their health by the way, and at last discovering, to their bitter disappointment, that dispensaries are not the sure avenues to private practice which they are often supposed to be. Again, the hospital surgeons *pretend* to perform their functions gratuitously, while in reality they are fleecing the students out of some thousands per annum.

That "the labourer is worthy of his hire" is a maxim for which we have the highest possible authority, and it is admitted and acted on with respect to all men except *doctors*. Who ever heard of a judge judging for nothing? or of a parson accepting not a *living* but a *starving*, for the gratuitous cure of souls? Who ever heard of a baker who fed, or a tailor who clothed the public, for ten years, before he began to charge anything, and afterwards did a handsome bit of *gratis* business now and then, just to keep up his character for liberality? Away with such nonsense! Let the medical practitioner be ever ready to yield his gratuitous assistance to

those *individuals* whose afflictions require, but whose means do not enable them to reward it; but we entreat our brethren to unite in their opposition to the *gratuitous humbug* in general. Let young practitioners rest assured that when a man offers his commodity, whatever it may be, for nothing, the conclusion deduced by men unaccustomed to such generosity will invariably be, either that the donor is a fool, or that the gift is not worth the having.

Of all the vocations by which men gain their living, we know of none that detracts so much from the pleasures and comforts of a man's life as medicine—none that entails on him so many anxieties and such heavy responsibilities; and yet, in the present constitution of the profession, the greater number of practitioners are in many cases reduced to toil in private practice for a smaller remuneration than that of the most mechanical labourer, and in the service of public charities, for nothing but the honour of being thought ninnies by those who are so obliging as to accept their charitable endeavours.

For our own part we shall not cease in our exertions to obtain for the private practitioner a legal title to a just emolument—for the medical jurist a reasonable remuneration from the State, in *all* instances where he is required to spend his time and exercise his talents in its service—and for the medical officers of public charities an adequate salary, which shall exempt them on the one hand from the miseries of unrequited and thankless exertion, and, on the other, from all temptation to the hypocritical knavery which extorts from inexperienced youths the remuneration of services ostensibly gratuitous.

—o—

FRENCH OPINIONS ON ENGLISH SURGERY.

IN the last number of the *Medico-Chirurgical Review*, there is an article headed *French Opinions upon English*

Hospital Surgeons and Surgery, in which some notice is taken of an article in this Journal, in which these opinions had been already noticed; and the article in our cotemporary concludes with recommending the Editor of this Journal “to give his reviewer what at Eton and Westminster is technically known under the name of a *bummer*,” in reward, we presume, for his audacity in informing the English professional public what a very eminent foreign surgeon had thought and published of our hospital practitioners. Madame de Stael, we believe, said that the opinion of foreigners might be considered and valued as that of a cotemporaneous posterity. Of course this very just general rule must have an exception wherever our personal friends—especially if we are dependant upon them—are concerned. In their behalf, the daring foreigner who presumes to censure their skill deserves to be kicked, and the reviewer who simply repeats the unfavourable report, must be *bummed*, in the elegant phraseology of our cotemporary! In return for the elegant “*lostum turdum*” observations of the reviewer of our cotemporary upon him of our fraternity, we were at first disposed to indulge our reviewer with the privilege he craved, of *bumming* (*metaphoricé*) the quarterly reviewer in our pages: we must confess we think he was fairly entitled to this indulgence, although we strongly suggested the imprudence of fighting with a sweep; for however the gentleman in such a rencontre may show the greater skill in the manly art of self-defence, he is sure to come off bedirted. But upon recollection, and upon looking at the lusty form of our reviewer, and his powerful arm of flesh, and considering how irritable the writer who *does* for our cotemporary is, where his friends are concerned, and therefore, perhaps, how still more waspish he would be concerning himself, under the castigation of our friend;] and respecting the

probable consequences of an actual encounter, we have interdicted the subject for the present, and our reviewer has agreed to drop the subject. But we will not promise a second time for our own tolerance, or our reviewer's contemptuous silence.

—0—

DEATH OF THE PORTSMOUTH CHOLERA
GAZETTE—APPEAL OF ITS EDITOR.

“Nil de mortuis nisi bonum.”

“When scoundrels, die let knaves bemoan
'em.”—*Brennan.*

SUCH of our readers as have heartily entered into the spirit with which this Journal has been conducted, and may have sympathised with the struggles its Editor has had against the monstrosity called the London Medical and Surgical Journal, published by H. Renshaw, Bookseller, Strand, and the motives which induced him at all hazards to quit the unhallowed connexion with that personage, will excuse our inserting the following paragraphs, which appears appended to a lecture on comparative anatomy by Mr. W. H. Rush, that has been widely circulated among the medical profession.

“Address to the Medical Profession.

“It will be seen by all who read the LONDON MEDICAL AND SURGICAL JOURNAL, published by a MR. RENSHAW, of the Strand, that a Lecture, introductory to the Science of Comparative Anatomy, delivered at the Westminster School of Medicine, has been inserted in the last number (181, vol. vii.) without the name of the Lecturer being affixed. As this Lecture occupies a considerable space of the Journal, and is upon a science extensively cultivated, the omission of the Name of the Lecturer may seem somewhat strange.

“As the Deliverer of the Lecture in question happens to be at the same time part Proprietor of the Journal, and its recognized Editor, he feels aggrieved at the underhanded mode in which Mr. Renshaw prevented his name appearing as the Author of the said Lecture.

“A plain statement of facts, representing the trickery by which Mr. Renshaw accomplished his scheme of suppressing the name of the Lecturer may not be inappropriate, or,

indeed, without some advantage to professional men; especially that portion of them who may be unfortunate enough to have dealings with a Publishing Bookseller.

“It may be in the recollection of the readers of the London Medical and Surgical Journal, that Mr. Renshaw has for some time been carrying on a warfare of opposition, with regard to what has been called his Journal: his opponent being DR. RYAN, who publishes a Journal under a similar title, but which, to all appearance, is destined to outlive the pamphlet of the former*. In consequence of like disputes connected with the dissolution of partnership between Dr. Ryan and Mr. Renshaw, having arisen between the latter and the Author of the Lecture, which is now submitted to the Medical Public in a separate form, he feels called upon to do this, in justice towards himself.

“The facts are these:—Mr. Rush, the author of the Lecture in question, consented to allow it to appear in the Journal upon the condition that his name should be affixed to it as the author. This Mr. Rush considered he had a perfect right to demand, from the fact of his possessing a large portion of the copyright of the Journal: and, indeed, the affair went so far upon this understanding, that the name of Mr. Rush actually appeared affixed to the Lecture in the PROOF SHEET,—but was afterwards, (mark!) before the numbers were struck off, expunged by a *sly trick* of Mr. Renshaw's, who is supposed to have marched most valiantly under the cover of the night, to the Printer's, when he well knew that the author would not be present, to insist upon his right to retain his name to the Lecture, or of withdrawing it altogether from publication in the Journal,—placed his veto upon it, and, both illegally and treacherously ordered the Printer to omit it; his motives for this procedure being simply, that a misunderstanding had occurred a few days prior to this *manly feat* on the side of Mr. Renshaw, with regard to the conducting of the Journal, Mr. Renshaw demanding to *act as sole Editor*. Yes, reader, sole Editor! although not possessing a particle of medical knowledge; and Mr. Rush, notwithstanding this presumption on his (Mr. Renshaw's) part, insisting on having the Journal conducted by a medical man, according to the terms in the articles of agreement.

“On the motives which stimulated Mr. Renshaw to condescend to this piece of double-dealing, Mr. Rush declines commenting, further than to submit, that a bookseller, being at the same time, from *his own confession*, too much engaged with his own trade, cannot be the best Editor in the world for a Medical Journal, which before he meddled with it, had been conducted by a physician of some eminence. The medical profession, it is not doubted, will properly estimate Mr. Ren-

* The pamphlet died on the 25th ult.—Ed.

shaw's interference, in thus surreptitiously withdrawing Mr. Rush's name from the heading of the Lecture. That injury was intended to the professional interests of Mr. Rush must appear plain, and Mr. Rush's motives in publishing this lecture separately are merely to neutralize that evil intention, and at the same time to caution medical men how they place their literary reputation at the mercy of an *Editorial Bookseller*. One word more. Mr. Rush's Lecture is not the first that has suffered from the mutilating propensities of this would-be Editor, to whom the Subscribers to the Medical and Surgical Journal are indebted for the deprivation of a portion of a course of Clinical Lectures by one of our most celebrated physicians, who, justly indignant at this supererogatory meddling, withdrew from the publication his able assistance and support.

"H. W. RUSH.

"1, Everett Street, Russell Square,
"July 20th, 1835."

"Mr. Rush's Reply to Professional Men, who have communicated with him on the subject.

"Since the before-going remarks were sent to press, Mr. Rush has received a number of letters from his professional friends, requesting an explanation from him with regard to the omission of his name from the lecture in question; some having asked him, if he was ashamed of his name being attached, others if the lecture had ever been delivered, and again others, who, knowing in part the *Editorial powers* of Mr. Renshaw, made a pretty shrewd guess, and asked *whether it was* not probable or at all possible, that Mr. Renshaw, by omitting the name of the author, thought that he might have been considered *not only Editor*, and Bookseller, but also *LECTURER*.

"Mr. Rush can only reply, to his numerous professional friends, by repeating the plain facts, which will be found in his public address, and then leave the profession to judge for themselves.

"In conclusion, Mr. Rush begs publicly to acknowledge his grateful thanks to all those professional men, who have taken upon themselves the trouble of enquiring into this trading like transaction, so as to free him from those suppositions, which otherwise might have been injurious to his reputation and character.

"July 21st, 1835."

It would be idle to deny the satisfaction we feel in announcing that the Journal, lately, as it appears, *Edited—Edited!*—by HENRY GRUNDY RENS-
SHAW, BOOKSELLER, STRAND! is at an end. It died of inanition—It never, for the honour of the profession, had the slightest patronage from the reputable

part of it. It had, as a part of a partnership stock, the right to the name under which the Editor of this Journal had originally commenced his weekly labours. It had, what but for the late catastrophe might be called *indomitable* obstinacy, and under all circumstances, it had impudence unparalleled to support it—and it had perhaps no little cash expended, to the great satisfaction of the pastry cooks. Its main ally—the very head and front of the pages edited! and revised! and corrected! by Henry Grundy Renshaw, Bookseller Strand, was a certain Dr. Graves, originally; and we regret to say it, introduced to English notice by us. Rats, they say, leave a sinking ship. How it was that Dr. Graves had not the sagacity of the just named animal, we cannot account for—'Tis true, however, he sank with the rotten hulk—and it will be quite amusing to such as take a fancy in the sport, to watch where it will rise. *Erinensis* is a very good ferret for the destruction of vermin. Perhaps St. George's Hospital is too new a building to be yet infested—at all events it will not be easy to catch him: the moment you are sure, "fond easy man"!—especially if he has promised—beware! a little huckstering, and he is clean escaped. But though Dr. Graves, sportsmanlike, was in at the Death, to vary our metaphor, the whipper-in must not be forgotten—Dr. Stokes once even hunted the pack, and in taking the field, so audible were his sohos and the crack of his whip, that with a good stethoscope you could actually hear him, though still the *craque-mont du cuir* was very dull. He was, however, a good sportsman, and if not a bold rider, must be allowed to have been a good Jockey—we once knew him unhorsed!

We will not further give utterance to our unmeasurable contempt for the whole party whose operations about a year ago are familiar to our readers—we leave our readers to chew the cud of

fancy on the foregoing address, promising that we can feel for any gentleman who has had the misfortune which Mr. Rush seems to have encountered (he should have known better), of experiencing, albeit in a minute degree, the conduct that has led to our emancipation. Little did malignancy expect that it would lead to the independence and flourishing condition which we at present enjoy.

—o—

CASES OF CONSTIPATION.

—

To the Editor of the London Medical and Surgical Journal.

SIR—I beg leave to forward you the two following cases of constipation for insertion in your journal, under the impression that they will be found interesting, not only as in the first thereof shewing the great quantity of various irritating purgatives that may be given under certain circumstances without any inflammatory effects ensuing, as we are naturally led to believe would occur alone from so long a constipation, but more so when conjoined with such active treatment as was employed to evacuate the contents of the intestines. Your constant subscriber,

HENRY BIRD.

15, Southampton Terrace,
Kentish Town.
July 28th, 1835.

M. P., aged 30, residing at Kentish Town, was seized in the night of the 27th March, 1834, with violent pains in the abdomen, for which I was called up to visit her. I found her screaming violently, although the pain experienced upon pressure was trifling, great fulness of the abdomen, head-ach, hiccup, nausea, and bilious vomiting; pulse 76, weak; tongue covered with a thick brown fur, and very dry; bowels had not acted for fourteen days. Warm fomentations to the abdomen.

Rx. Hydr. submur. gr. vj;
Pulv. opii. gr. j.

Fiat pilula statim sumenda.

Rx. Infus. sennæ, ℥ iij;
Magnes. sulph. ℥ j;
Spt. ammon. ar. ℥ ss;
T. jalapæ, ℥ ij.

Misce.

Fiat haustus semihorâ port pilulam sumendus et quartis horis repetendus.

9 A.M. Pain abated, but no evacuation.

Rx. Ext. coloc. co. ℥ ij;
Magnes. sulph. ℥ ij;
Decoc. hordei, O ij.

Fiat enema stat injiciendum.

This passed very readily, and remained about twenty minutes, returning unaccom-

panied with any fæcal matter; vomiting increased, in other respects much the same. I was now informed she occasionally indulged in copious potations of gin, and as she was very bilious, I ordered as follows:—

Rx. Hydr. submur. g. x.

In pilulæ ij, secundâ horâ sumend.

Rept. enema post horas tres si opus sit.

1 P.M. Much the same—no stool—pain returned. Mustard sinapism: she continued in this state until 9 P.M., having taken ℥ j of calomel.

Rx. Ol. croton. m. iij;

Micæ panis, gr. iv.

Fiat pil statim sumend et rept secundâ horâ donec alv. respond.

28th.—8 A.M. Has taken fifteen minims of the oil without the least relief; I made an examination per rectum, which was perfectly free from scybalæ.

Rept. enema adde ol. croton. m. vj.

10. No stool—pain severe.

Rx. Ext. elaterii, gr. xij;

Ext. coloc. co. ℥ j;

Ol. carui, m. vj.

Fiat pilulæ, vj, cap. i, singulis horis.

6 P.M. Has taken all the pills, but all of no avail—great febrile heat over body—clammy perspirations over face—violent head-ach. Pulse 84, weak.

Rx. Aloes socot. gr. v;

Acid. sulph. gtt. j.

Fiat pilul. cap ij, singulâ horâ.

10 P.M. Has taken four doses of the pills; the bowels have just acted most copiously, and very quick in succession; she was up and about in two days more, not being attacked with any inflammatory symptoms; as I had reason to fear. She says she has been subject to these attacks for some years past, and being an obstinate woman, she will not try to prevent the recurrence of them. I have since this attended her three or four times, and found the latter form of pill speedily procure a stool.

Robert Luck, butcher, aged 35, full habit of body—had not passed a stool for eight days when he procured a letter to an hospital, and was made an out patient thereof; the physician, for some cause or other, ordered him to be cupped on the loins, and gave him some colocynth pills, requesting him to come again that day week (Thursday): the man's bowels however did not act, his pills were all gone, and he remained in statu quo, without evacuation, medicine, or advice. Sunday he was unable to rise from his bed, when a gentleman called and related the case to me. What! I thought, is this the boasted charity of the British country? the well regulated public hospitals? to leave a man for seven days longer with a constipation of eight days previous, without knowing or caring one jot whether the man was relieved or not, or whether the medicine had produced the desired effect.

Sunday, July 12th.—11 A. M. I found him turning and tossing in bed, retching violently without expelling any thing from the stomach, breathing oppressed, great nervous irritability, head-ach, pulse 96, full, tongue furred and brown, great heat, violent pain on pressure.

Venæ sectio, ζ xvj. (Mustard cataplasm).

R. Hydr. submur. gr. vj;
Pulv. opii, gr. i.

Fiat pil. stat. sumend.

R. Haust effervesc. ad libitum.

R. Ol. ricini, ζ ij;
Aq. puræ, Oij.

Fiat enema.

2 P. M. No stool, pain much relieved, blood buffed and cupped, nausea diminished, pulse 80, compressible. Pt. pil. cal. secundis horis.

10 P. M. No stool. Pt. enema et pil.

Monday the 13th. 6 A. M. Passed a very bad night and no stool.

R. Ol. croton. m. iv, statim sumend.

10 A. M. All of no avail, pain very urgent on pressure.

R. Aloes soc. gr. v;
Acid. sulph. gtt. i.

Fiat pil. cap ij, singulâ horâ.

I was unexpectedly called down to Oxford, and was obliged to procure the assistance of a friend, who informs me that after he had taken four doses of the pills, the bowels acted freely. He ordered him also

Hirudines xij, abdomini.

Tuesday—3 P. M. I saw him on my return: he is now labouring under an attack of inflammation.

Hirudines xx. Empl. lyttæ postea.

Pt. enema ut supra.

In the course of a week he was able to walk out, and is now quite convalescent.

This latter case shews the peculiar idiosyncrasy of constitution; he was an abstemious man; the purgatives employed were not near so active as in the former case, but my experience leads me to believe, that in persons where the liver becomes affected from the abuse of ardent spirits, inflammation more rarely occurs after constipation, and the irritating means sometimes necessary for the relief thereof, than, under contrary circumstances, and that in all cases of inflammation of any organ or part coupled with such hardened state of liver, the treatment necessary is more active and uncertain.

I have had several cases of constipation for seven or eight days, and the relief obtained by the aloes when conjoined to the acid has been very speedy, even after the other cathartics have failed. Why the acid should increase its action I am at a loss to account for, although I am fully satisfied that such is the case.

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from page 16.)

Treatment of Permanent Stricture of the Urethra.—Though stricture of the urethra must have occurred in the earliest ages, the first allusion to it in the writings of the primitive physicians is, according to my researches, to be found in the works of Gallen. In describing the causes of retention of urine, he includes compression of the neck of the bladder, and carnosities in the urethra, which required the use of the sound for their removal*.

A Spanish physician, named Aldareto, who was Professor at Salamanca, was said to have been the inventor of bougies, and taught their use to Amatus, of Portugal†, who introduced them into practice. Others held that Phillipus, a Portuguese empiric, was the real inventor; but this is extremely improbable. Andrea Laguna, or Lacuna, of Sevogovia, employed them very much in 1551, as also did Alphonso Ferri at the same time. This writer maintains that bougies were known to the Greek, Alexander, whom Astruc contends, resided at Tralles, or Trallia. Vega followed in 1552. Diaz recommended caustics, and, according to Amatus, also metallic bougies.

Fabricius described bougies made of horn, which were to be softened in warm water before their use. The next instrument of this kind was made of fine silver wire turned spirally. In 1603, Henry the Fourth, of France, was cut for a caruncle, by Mayerne; but, as this method failed, Layseau was consulted, and he used an escharotic bougie, composed of different ingredients, among which was powdered saving‡. Bougies of various sorts were generally used, until the time of Mr. Hunter, when he concluded that the destruction of the obstacle by caustic was the best way of removing it; first, he introduced a canula down to the stricture, and in this was concealed a stilet with a piece of nitrate of silver at the end of it. He then proposed to fix a piece of caustic at the end of a wax bougie, and this he called the "armed bougie." His nephew, Sir E. Home, strongly recommended this instrument; and it has been much used in this country for the last forty years. It is, however, liable to fatal

* De Loc. Affect. c. 1, and De Compos. Med. l. 3.

† Amat. Lusitan. cent. iv. 154I.

‡ F. Roncalli applied the lapis infernalis by means of a tube, in the commencement of the eighteenth century. Exercitatio agens novum Methodum extirpandi Carunculas et curandi fistulas urethræ. Brixia, 1720.

objections, as will appear hereafter. Mr. Whately proposed caustic potass instead of nitrate of silver. In using either instrument, however dexterously used, the healthful part of the urethra was cauterized, the mucosity of the canal loosened the caustic, which often fell into the urethra, and of course destroyed all parts with which it came in contact.

The canula and stilet proposed by Mr. Hunter, served as a model for the instruments of Petit and Delpech, which were a cylinder of nitrate of silver solidly fixed in a gum elastic sound, and uncovered at the anterior extremity, with a layer of tallow on its sides, to prevent it acting on the sound surface of the urethra. This was passed without a conductor, and was nearly as objectionable as the armed bougie. Civiale proposed a conductor, and his instrument is very similar to Ducamp's. Lallemand at first passed an armed bougie through a gum elastic sound. All these contrivances could act on the anterior part of the stricture only, often cauterized healthful structure, and required to be re-applied several times. False passages were frequently made, and Delpech described a case in which the bougie passed into the rectum. By this plan we can only act on the centre of the stricture, while a superior mode is to cauterize the apex, and gradually descend to the base of the stricture. An instrument for this purpose is now happily used.

In 1822, the Academy of Sciences, of Paris, proposed for a prize essay, "A treatise on retention of urine caused by contractions of the urethra, and the means by which such obstructions of the canal could be completely destroyed." The successful essayist was M. Ducamp, who, after a most scientific and graphic description of the causes and pathology of stricture, proposed an instrument for its complete destruction. This he called a *port caustique*. It consists of a flexible catheter, about eight inches in length, which contains a stilet, the end of which is composed of platina or gold, into the side of which the nitrate of silver is fused with the flame of a candle.

The superior advantage of this instrument is, that it enables us to apply caustic with ease and certainty to the stricture only, and there is no danger of the escharotic falling into the urethra or touching the sound part of the canal. No matter whether the stricture is superiorly, inferiorly, laterally, or encircling the urethra, this instrument can be applied, because the inner tube or stilet, in whose side the caustic is permanently fixed by fusion, is so small as to pass into the opening of a stricture or against the projection of it, beyond the end of the outer tube. The caustic is applied for about a minute, produces very little pain, and causes no discharge. On the next day the patient passes urine in a fuller stream, with less force and pain, provided there is no other stric-

ture. By this method there is no hæmorrhage, no false passage, no retention of urine. The slough comes away on the second day; the operation is repeated on the third, and reiterated until a bougie of No. 6 can be used, when the cure is completed by one which is termed a bellied bougie.

When the stricture is situated five and a half or six inches from the orifice, it is difficult and perhaps impossible to reach it with a straight instrument. To obviate this, M. Lallemand has invented a curved *port caustique*. His plan is to pass a larger instrument every time, and thereby to facilitate the cure. But straight instruments are now easily passed into the bladder by lithotritists.

The instruments of M. Ducamp are modified by Mr. Benjamin Phillips, who has kindly allowed me to illustrate his improvements; the plates of which will appear in our next number.

Mr. Phillips has, however, found in several cases that the slightest application of the caustic as a stimulant, and not as an escharotic, is sufficient to facilitate the absorption of a stricture by means of the white flexible metallic bougie, and he assures me that he generally succeeds in removing stricture with this instrument. I can bear testimony to this statement. In fact, Mr. Phillips is of opinion that the free use of caustic is very rarely necessary; but it ought to be applied by means of the *port caustique*. This instrument is now generally used in France, and also by Mr. Costello in this country.

The discovery of this instrument has given rise to a controversy as to the inventor. The French award that merit to M. Ducamp, and the English to Dr. Arnott. The proofs in favour of the latter are offered by his brother, Dr. Arnott, the celebrated author of the *Elements of Physics*, on whose statements the fullest confidence must be placed. I shall quote his statement, to which is prefixed a short account of the nature and treatment, which is so plain that every one may and can comprehend it. I extract it from his *Elements of Physics*. It is as follows:—

"Obstructions in the urethra are generally consequences of an inflammation, which has destroyed the dilatibility of a part of the canal. They appear as if a thread, or a bit of tape were tied round it, so as to narrow its calibre.

"Constant irritation, often destroying the general health, fits of fever, broken rest, and even death from total suppression, have been common consequences of this deplorable disease.

"Until within a recent period, the treatment of such obstructions was pursued very generally, according to a blind routine.

"They were attempted either to be bored open by wedges, called bougies, often of doubtful and tedious operation, or to be destroyed by caustic passed down to them in

the end of a bougie, which caustic often hurt the anterior part of the canal, or ate out false passages about the stricture, or opened blood-vessels, and caused dangerous hemorrhage.

"Struck by the defective state of this branch of the healing art, the author had bestowed considerable attention upon it during the years of practice which he spent abroad, and he then contrived and tried several new means of relief.

"These were afterwards brought more extensively into use and improved, and others were added, by his brother, Dr. James Arnott, superintendant surgeon in the service of the Honourable East India Company, who gave a minute account of them in a Treatise on Urethral Diseases, and a supplement, published in the years 1818 and 1820. They have become, perhaps, still better known in France than England, through the work of Dr. Ducamp, which described them; and which, having been submitted to the French Institute, and most favourably reported upon by the appointed examiners, soon became a standard treatise: in France, also, the philosophy of mechanics has been more studied than generally by English surgeons. It is painful to be obliged to add here, that Dr. Ducamp concealed the fact as regarded these instruments, and the views of disease and treatment which suggested them, of his being only a translator. The imposition was not discovered at the time of his death, which

appened two years afterwards, hastened apparently by the fatigues of practice, which the report of the Academy brought upon him. The author has had so much pleasing intercourse with enlightened and honourable Frenchmen, that he grieves to have this fact to relate.

"The objects aimed at by the new means, were to ascertain the exact condition of the diseased canal, to facilitate the passing of instruments in cases of difficulty, and to effect a permanent cure.

"The following seven means may be particularized:—

"1st. An examining sound: being a bougie, with the point formed of a softer tenacious material, in which fibres of cotton or silk are mixed to prevent any portion from being broken off or detached during use. This sound pressed against the obstruction, takes a correct impression of its anterior face, and shows the magnitude and exact position of the remaining opening.

"2nd. An expanding or dilator sound, which is a small tube with a dilatable button at its extremity. The button consists of a little bag, empty while it is passing through the stricture, and filled with fluid when it has reached beyond it.

"It readily discovers any other strictures beyond the first, and the state of each.

"3rd. A conducting canula or tube, open at both ends.

"It is passed down to the stricture, for the purpose of supporting and directing small bougies seeking entrance through very narrow strictures, or of guarding the caustic bougie in its approach to the place of its action.

"4th. In cases where the attempt to open the passage has failed by all common means, a conducting tube is first introduced, and, through it, six or more small bougies are then passed side by side, so as to probe the whole face of the stricture at the same time.

"It is thus scarcely possible that the opening should not be found.

"5th. Were even this means to fail, the conducting tube may be filled with water, under any degree of pressure; which water will either open the passage for the small bougies, or will itself act as the sharpest and most insinuating of all instruments. The stricture, by whichever means opened, will then allow the urine to escape.

"As patients might fear that the water forced towards a bladder already too full, would only increase the evil, Dr. J. Arnott waited for more numerous proofs of the utility and safety of the practice, before strongly recommending it. Dr. Amussat, of Paris, has lately published a statement of numerous cases of retention thus relieved.

To be continued.)

MEDICAL BOTANY.

(PLATE III.—THE AMYGDALIS COMMUNIS.

Amygdalus communis, Wild. g. 981; Spr. 1815. *Icosandria Monogynia*. *Nat. Ord.*—*Pomaceæ*, Lin. *Rosaceæ*, *Sect. Drupeæ*, Juss.

Sweet almonds are of greater use in food than in medicine, but they are reckoned to afford little nourishment; and when eaten in substance are not easy of digestion, unless thoroughly comminuted. They are supposed, on account of their unctuous quality, to soften acrimonious juices in the primæviæ. Peeled sweet almonds, eaten six or eight at a time, sometimes give present relief in the heart-burn.

On triturating almonds with water, the oil and water unite together, by the mediation of the albuminous matter of the kernel, and form a bland milky liquor, called an emulsion, which may be given freely in acute or inflammatory disorders. As the bitter almond imparts its peculiar taste when treated in this way, the sweet almonds alone are employed in making emulsions.

Several unctuous and resinous substances, of themselves not miscible with water, may, by trituration with almonds, be easily mixed with it into the form of an emulsion, and are thus excellently fitted for medicinal use. In this form camphor, and the

resinous purgatives, may be commodiously taken.

Almond oil is supposed to blunt acrimonious humours, and to soften and relax the solids: hence its use internally in tickling coughs, heat of urine, pains and inflammations; and externally in tensions and rigidity of particular parts. The flour from which almond oil has been expressed is in common use as a cosmetic soap.

Bitter almonds have been found poisonous to dogs and smaller animals. Nevertheless, bitter almonds are every day used in cookery, on account of their agreeable flavour; but there are some constitutions in which the smallest quantity produces urticaria, and other unpleasant symptoms. The medicinal use of bitter almonds is of very ancient date. Bergius revived their administration in ague. Hufeland also asserts, that when eaten freely for several weeks, tape-worms were expelled, which have resisted every other remedy. In several of the foreign pharmacopœias there is a formulæ for water of bitter almonds, which in every respect coincides with cherry laural water. The oil of bitter almonds is extensively used by compounders of liqueur, for making noyau and ratafia, though its effects are well known to be very deleterious.

Case of Cholera—Fatal termination in less than Seventeen Hours. By J. C. Atkinson, Esq., M.R.C.S. and Licentiate of the Apothecaries' Company.

Mrs. T., aged 25, of a leucophlegmatic habit, slender, married about four months, residing at —, Westminster, was seized, about three o'clock, P.M., on Tuesday, the 28th inst., with violent cramps in the abdomen, having been relaxed for the four preceding days. I was requested to see her between seven and eight o'clock, and found her labouring under severe spasms in the bowels, more especially in the region of the liver, but not in the upper or lower extremities. There was severe vomiting of a yellowish fluid, with a small quantity of mucus, and profuse diarrhœa, with thin yellow dejections mixed with dark-coloured scybala. The pulse was small, frequent, and easily arrested, ranging between 120 and 130; the respiration frequent; temperature of the body very much reduced; extremities cold and covered with clammy perspirations. There was no lividity nor shrivelled appearance on the skin: the voice was altered—it was low and whispering: the tongue was cold, and so also was the breath.

The medicines employed were antispasmodics, ether, opium, camphor, &c., and the astringents, a strong decoction of hæmatoxylium, and one grain of calomel every ten minutes, as recommended by Dr. Ayre. Two table-spoonsful of muriate of soda in

a tumbler of water were given as an emetic, and were followed by re-action.

Notwithstanding all remedies, she expired on Wednesday morning at a quarter to eight o'clock, in less than seventeen hours from the commencement of the disease.

It appears to me that this case was different from diarrhœa or English cholera, as it was characterised by different symptoms, and that it was perhaps a modified form of the more fatal epidemic cholera. It is well known that the latter disease was often preceded by diarrhœa, and not invariably attended with blueness or rice-coloured evacuations. The case, at all events, appears to me to be worthy of record, on account of its sudden and fatal termination.

Westminster, July 29, 1835.

REMARKS

ON THE

TRIAL OF ROBERT REID,

FOR THE MURDER OF HIS WIFE,

BEFORE THE HIGH COURT OF JUSTICIARY,
AT EDINBURGH,

On the 29th of June, 1835.

By JOHN FLETCHER, M. D. F.R.C.S.E.

LECTURER ON PHYSIOLOGY, AND ON
MEDICAL JURISPRUDENCE.

MANY of our subscribers and friends have lately inquired of us the cause of the cessation of Dr. Fletcher's admirable lectures; but the following remarks afford a satisfactory answer. It will appear by the sequel, that our able and learned contemporary had most humanely acted as medical adviser to an unfortunate man, charged with the horrible crime of murder, was engaged for weeks past, and succeeded by real science in saving the life of a fellow creature. The remarks on the trial, which we now submit to our readers, are replete with the deepest interest, and will serve as a beacon to future medical jurists to avoid falling into error, by depending upon the assertions of those ignorant and illegal practitioners, who so often appear as witnesses in courts of justice. It is lamentable to reflect upon the fact, that human life may be sacrificed by the evidence of such men, which, strange to say, is still admissible in our law courts. The fault, however, lies with the legislature and our medical corporations. They allow any person who has the audacity and impudence to style himself physician, doctor, surgeon, or accoucheur, to appear as a witness to elucidate the most abstruse and difficult questions as to the cause of death. In other countries, for example, in France, Germany, Prussia, Italy, &c., no man is allowed to appear as a medical witness, unless distinguished for his knowledge and acquirements regarding the subject under investigation. And this is perfectly wise, when we consider that the

life of a fellow creature is to be preserved or destroyed by the result. We might cite many unfortunate cases which occurred in this country, in which life—we grieve to indite the fact—was sacrificed by the ignorance of medical witnesses, who assumed the titles of the profession, and also by the ignorance of judges and lawyers on medical questions*. We however refrain, but cannot help observing, that had the coroner or sheriff been a well educated and scientific medical practitioner, or had such an enlightened and learned individual as Dr. Fletcher been coroner or witness at the inquest hereafter mentioned, the unfortunate prisoner, whose name is recorded in the following remarks, would never have been put on trial for his life, or have had so miraculously escaped the gallows. The truth is, that coroners ought to be medical practitioners, or at least have a scientific medical adviser. If this were the custom—and we beseech our legislators to consider the subject duly—or if barristers were advised by such able men as Dr. Fletcher, when defending criminals, our firm conviction is, that a large proportion of the accused would be properly acquitted, and nine-tenths of the medical pretenders who figure as witness—and the majority of witnesses are of this class—would be exposed to the scorn of the public.

Nevertheless, we see such individuals as Mr. O'Connell and Mr. Warburton opposing the English Coroners' Bill, and causing its rejection in this session of parliament—the first on the grounds of the exorbitancy of a fee, of one or two pounds to a medical witness! on the score of jobbing; as if personal liberty, and finally human life, were to be put in jeopardy for such a paltry consideration. The latter opposed the bill on the grounds of the mode of election of the coroner. Entertaining, as we do, in general, the sincerest respect for the good intentions of both these legislators, we can-

* Mr. Amos, an English barrister of eminence, acknowledged this fact in his lectures at the London University, published in the Medical Gazette.

not help remarking that they have gained few laurels by their opposition to the bill in question; and we suspect rather strongly, that the future historian will record the obliquity of their mental vision on this occasion.

Thanks to Mr. Wakley, with whom we never agreed on many points of medical reform, for having clearly exposed the subject in its true light, and completely silenced Mr. O'Connell.

Mr. Wakley well observes, that the legislature was always ready to enact laws which allowed barristers to travel in coaches and four, and receive fees of five guineas a day; but when medical practitioners were concerned, though they had to examine putrid dead bodies, after the lapse of days, weeks, or years, which required six or eight hours' labour and rendered the operators liable to the danger of imbibing fatal disease, then a pound or two was considered an exorbitant remuneration!! Mr. W. also added, that in one case of an inquest at the London Hospital, an *attorney coroner*, at the head of the jury, found the supposed defunct *eating oysters*! Mr. O'Connell, with his usual forensic tact, replied, that this exceeded any thing which happened in his own country. Much to his credit, he gave no farther opposition to the Coroners' Bill, but Mr. Warburton, the friend of medical reform, gave it the *coup de grace*, or, to use a free translation, the death blow. Let both these legislators peruse the following pages—and we shall afford them the opportunity—and then reconcile to their philanthropy and independence, their hostility—we shall use no harsher term—to the English Coroners' Bill; though medical practitioners are allowed four and five guineas for attending inquests, and most properly so, in Ireland. Leaving these members of the Collective Wisdom to consider the foregoing and following facts, we turn with sincere pleasure to the beneficent exertions of our noble and disinterested profession, in which sordid gain has never had any influence. We place before them the brilliant example of Dr. Fletcher, in exculpation of an innocent plebeian, and saving his life. We well know that Mr. O'Connell has repeatedly given his valuable services, without any reward, save the pleasure of doing good to his unfortunate countrymen; but he must excuse us for speaking of him as the opponent to the introduction of Mr. Crisp's English Coroners' Bill.

We place his example before all classes of the public, legislative, judicial, and professional, with the hope that many will imitate it. If it needed support—and it does not—we should allude to the late Bristol case, in which conviction, after a lapse of fourteen months, followed the result of scientific medical evidence of an exhumed body, and without the slightest pecuniary remuneration there. We cannot but ob-

serve, without meaning disrespect, that neither clergymen, judges, lawyers, or senators, act *so disinterestedly*; and we offer this remark, as they are always ready to defend the preposterous custom of requiring the medical profession to give their services *gratuitously*.

In fine, the following remarks offer an excellent lesson to medical men, and prove how cautious they should be in receiving the testimony of every fool who calls himself physician or surgeon, and is admitted as such by the law, "which is the perfection of reason." Even our ablest physicians are misled by such witnesses. Thus, Professors Christison and Traill were duped by the evidence of an ignoramus named Williams, as appears by the following remarks. They should have known better. Under a false impression, their evidence went to hang an innocent man. When a prisoner is placed at the bar, and a verbose indictment read, three-fourths of which is either tautology or fudge, the judge, jury, lawyers, and medical witnesses, feel disposed, in most cases, to condemn the accused without a hearing. The clerk of the crown reads the indictment with solemn emphasis; he charges the accused, in many cases without reason, of having, "without the fear of God before his eyes, and instigated by the devil, riotously, illegally, and unlawfully inflicted divers and sundry wounds upon the deceased," though no wound was in reality inflicted; and "against the peace of our sovereign lord the king, caused the death of A. B." Judge, barristers, jury, auditors, and witnesses all look grave, and cock their sapient ears at the charge, though in truth the deceased died a natural death, and was subjected to no violence whatever. The trial proceeds, a pretender to a medical title swears, as clearly as that the moon is made of green cheese, that the accused is guilty of the death. Better informed medical witnesses are called; they base their evidence upon the swearing of a person who would not, or could not distinguish the liver from the heart: but credulity influences all concerned; they are disposed to consider the accused guilty, and they sometimes allow themselves to be stultified, and a fellow subject sacrificed.

Thus, it has been proved that arsenic blackens a knife, and on this evidence an innocent prisoner is executed. It has been sworn that an infant born at the age of six months is not viable, and a woman who commits infanticide is acquitted, though infants born at that period have arrived at maturity. It has also been sworn that a woman after delivery could not walk across the apartment in which she lay, and appear at a window, though we have known one travel forty miles in a coach, between the delivery of one infant and another. It has also been proved, that a woman at the age of sixty cannot be a mother, and im-

mense property passess from her son, though Haller and others record cases of women at the age of seventy who brought forth a child. We might multiply cases of this kind to infinity; there is not a day in which examples are not to be found in the newspaper reports; and all shew the necessity of appointing medical coroners, or medical advisers to coroners, barristers, or judges. This is the custom in France and other countries. The benefits accruing to the public would be, that the coroner's warrant would not improperly deprive an accused individual of his liberty, for an hour, week, or months; and secondly, that barristers, jurors, and judges would receive correct evidence, and decide accordingly. It is a monstrous error to admit uneducated medical practitioners as witnesses at either civil or criminal trials; none but legally qualified, and in large towns and cities none but the most learned, scientific, and experienced, ought to be admitted. If a law to this effect were enacted, a vast deal of injury would be saved to every class of society. It is to be hoped that the wisdom of the legislature will, ere long, lead to the accomplishment of this important and necessary improvement.

Were legislators to peruse Dr. Fletcher's remarks on the case we are about to submit to our readers, they could not fail to perceive the expediency and necessity of requiring the testimony of the most learned and experienced medical men in all judicial investigations, from the highest to the lowest.

We reprint Dr. Fletcher's Remarks on the Trial of Robert Reid, for the good of our profession and the public, and we feel convinced that they will do a vast deal of benefit to both.—Ed.

Having ascertained that a strong impression exists in the public mind that the acquittal of Robert Reid of the late charge of murder was undeserved, and being given to understand further, that certain points in the medical evidence in his favour may soon be made the subject of express animadversion, I think proper, having acted as medical adviser to his counsel, to state, in few words, my views of the general merits of the case, before the subject becomes confused, as it is probably destined to be, by the agitation of certain isolated and abstract points connected with it, and encumbered with the desultory *verbiage* almost inseparable from such discussions. As my name does not appear upon the face of the proceedings at his trial, I might very well have declined this task; but, engaged as I was in the business, I cannot help feeling desirous of removing the prejudice which I find so generally entertained against Reid; a prejudice founded, I am persuaded, upon the incompetency of the public in general—owing to the very meagre account of the exculpatory evidence contained in the daily papers—fully to appreciate some of the chief circumstances which

tell in his favour, while all are abundantly capable—from the comparatively full account given of the evidence on the other side—of estimating every point which has an opposite tendency. It is my intention then to present, in the following pages, a collective view of the general merits of the case in question, as they appear upon the face of the trial, leaving it with the reader afterwards to determine whether I had any grounds for interesting myself, as I did, in this man's behalf, or whether he should have been left, without a suggestion on his side, to that fate which otherwise might have awaited him. I need hardly say that I am not responsible for any part of the medical evidence given either against Reid or in his favour; but I will not shrink from my share of any imputation which may be cast upon the latter, where I feel satisfied that it was well founded. I have no hesitation in declaring thus *in limine* that, while I regard the medical evidence for the crown, in this case, as in most points exceptionable, and in many disgraceful in the extreme, I look upon that for the accused as in general highly satisfactory; and, without taking upon myself to father to the letter every statement made by the medical witnesses on the side of mercy, I entirely coincide in the general bearings of these statements, and in the conclusions to which they tend*.

* On some occasions, when the medical opinions given in a case of this description have been more or less contradictory, it has been objected afterwards by the one party that the conduct of the other was un courteous and uncandid, in their not having previously communicated with their professional brethren, and stated to them the grounds on which they intended to oppose them; but I beg to observe that no reproach of this kind can attach to me in this instance. On the very first day of my engaging in this affair, I waited personally on the Professor of Surgery in the University, the colleague of two of the principal witnesses for the crown, stating my doubts, and requesting his opinion on some of the chief points of the case; and it was by his friendly advice that I acted as medical counsel in this business, instead of allowing myself to be cited as a witness. I afterwards prepared a long list of questions, calculated to elicit the chief facts which I was desirous of making out at the trial; and I have reason to believe that these gentlemen were fully precognosed, long before the trial took place, on the substance of these questions, by the counsel for the prisoner. In a personal interview also with Dr. Forbes, another of the medical witnesses for the crown, the day before that on which the trial was first expected to come on (Monday, 16th March), I conversed with him freely on the various points of medical evidence afterwards brought out at the trial, and gave him a card of introduction to an accomplished anat-

As the following remarks are intended for the non-medical, as well as the medical public, I shall make them as simple and as concise as possible, avoiding, as far as I can, all technicalities and all abstruse medical discussions, and confining myself strictly to the naked case before us, any allusions to other analogous cases—which might very easily have been made—being calculated, with people in general, rather to obscure than to illustrate the subject immediately in hand.

It would have been certainly a great advantage had an authenticated account of the trial preceded the comments which I am about to make. Such an account will in all probability soon appear: but in the meantime, I do not despair of being able to make the following analysis of the evidence perfectly intelligible to those who have seen the accounts of the trial contained in the public papers; while, for the sake of those who have not, I have thought it expedient to subjoin an extract from the indictment, as given by these papers, and a list of those witnesses to whose statements I shall have occasion to refer, both for the crown and for the prisoner, in the order in which they severally gave their evidence*. With re-

gist in this city, who was so obliging as to accompany him on the Sunday—as the time was pressing—to his museum, and to point out to him, on wet preparations, the anatomy of the parts on which he was to give evidence. Had the trial taken place at this time, no medical witnesses whatever for the prisoner would have appeared, his counsel being prepared to rely for the defence entirely on the cross-examination of the crown witnesses: but, in the long interval which elapsed before the actual coming on of the trial, it was considered expedient by the counsel and agent for the prisoner to have, if possible, some positive medical evidence in exculpation; and it was in consequence of the answers which they received to the identical series of questions the substance of which was discussed with the crown witnesses from the medical gentlemen who appeared on the opposite side, that the latter were cited. Nobody therefore can complain of having been taken by surprise in this business. All must have been aware from the first, not only of my being engaged, but also of the precise line of defence which was to be set up; and if any further communication were desirable between the parties, it was surely as much the business of the crown witnesses as that of those who entertained a different opinion, to seek such communication, which certainly would not have been refused.

* “On Monday (29th June, 1835) the continued diet was called against Robert Reid, tailor at Pathhead, accused of the murder of Elizabeth Arnot or Reid, his wife. The indictment set forth that he ‘did, on the 19th or 20th of September, 1834, wickedly

spect to the *ipsissima verba* of the witnesses to which I refer, they are copied from verbatim notes of the proceedings taken during the trial, and strictly corresponding, in all important points, with my own remembrance of the evidence given.

The presumption of the guilt of the prisoner in this case appears to have rested principally upon the following circumstances, medical and moral, from the former of which the crime, and from the latter the criminal, were inferred. To the *medical circumstances* belong, 1. The posture in which the corpse of the reputedly murdered woman was found. 2. The discoloration of the back of the neck and spine. 3. The alleged presence of coagulated blood in the discoloured parts. 4. The reputed rupture of one of the external jugular veins. 5.

and feloniously attack and assault the said Elizabeth Arnot or Reid, and did, with an axe, or with some other instrument to the prosecutor unknown, strike her one or more severe blows upon or near to her neck, and did thereby, or by some other violent means to the prosecutor unknown, fracture and dislocate one or more of the vertebræ in or near the neck; in consequence of all which, or part thereof, she immediately or soon thereafter died; or did, by strangling or suffocating her in some manner to the prosecutor unknown, or by some other means to the prosecutor unknown, then and there wickedly and feloniously put her to death; and the said Elizabeth Arnot or Reid was thus murdered.’ To all of which the prisoner pleaded not guilty.”

Witnesses for the Crown referred to in these remarks.—Isobel Young, of Pathhead; Mrs. Tod, ditto; Mrs. Chisholm, ditto; Cherry Manners, ditto; Mrs. Ness, ditto; John Arnot, ditto; Mrs. Fife (wife of John Fife), ditto; John Piggot, ditto; Thomas Grieve, of St. Clairtown; Charles Walker, Baron Bailie of Pathhead; C. C. Williams, surgeon, of Dysart; Dr. Forbes, of Dysart; Professor Christison, of Edinburgh; Professor Traill, of Edinburgh.

COUNSEL.—The Solicitor-General (Cunninghame), John Shaw Stewart, and George Napier, Esquires, Advocates-Depute.

AGENT.—David Cleghorn, Esq. W. S.

Witnesses for the Prisoner.—* John Fife, of Pathhead; * Mrs. Thomson, ditto; * Mrs. Crichton, ditto; * Mrs. Lenny, ditto; * William Duncan, ditto; Mrs. Finlay or Smith, of Kirkaldy; Henry Russel, of Pathhead; Mrs. Gray or Smith, Jailor of Kirkaldy; Mrs. Wilson, of Pathhead; Michael Slater, sheriff-officer of Kirkaldy; James Fife, of Pathhead; Dr. J. R. Robertson, of Edinburgh; Professor Lizars, ditto; Dr. Mackintosh, ditto.

(Those marked * were in the list of Witnesses for the Crown.)

COUNSEL.—James Anderson, and G. H. Pattison, Esquires, Advocates.

AGENT.—William Duncan, Esq. W. S.

The fracture and luxation of one of the vertebrae of the neck; and, 6. The discovery in the apartment of an instrument competent to inflict these supposed injuries. To the *moral circumstances* belong, 7. The alleged bad terms on which the prisoner lived with his wife, and his occasional threats of doing her some injury. 8. Her frequent complaints of his bad usage of her in general, and in particular her exclamation in the middle of the night preceding the day of the supposed murder. 9. The alleged agitation of the prisoner when taxed with the murder, his ambiguous expressions when asked of what complaint his wife had died, and his subsequent declaration of satisfaction at being released from her. 10. His denial of having been at home at two o'clock on the day of the supposed murder. 11. His haste to procure a coffin for the corpse; and, 12. His alleged confession of the murder.

Never was there a case on which, to all appearance, a stronger, a more consistent or a more unbroken chain of circumstances, calculated to produce in every mind a conviction of guilt, was brought to bear upon an unfortunate individual; and so impossible did it in fact appear to me, at the first view of the case, as presented to me by the indefatigable agent for the prisoner, Mr. Duncan, to find a loop to hang a doubt on, that I was tempted to decline engaging in it at all. A closer inspection of the matter however tended materially to alter my opinion; and let the reader only suspend his judgment of the whole of this chain till each of the links has been examined, and he will probably find, as I did, that there never was a case in which an apparently strong, consistent and continuous series of circumstantial evidence of guilt was in fact more feeble, more incongruous, or more interrupted. On the other hand, in going attentively through the evidence purporting to substantiate the presumption of guilt—to say nothing of that the declared object of which was to lead to a different conclusion—so many considerations at every step present themselves, adapted, not only to stagger our confidence in our first impression, but to suggest and inculcate an opposite belief, that we find ourselves gradually becoming converts to the latter; and if we do not at last confidently say that the woman died a natural death, we are at least disposed to express great doubts that she was murdered. I shall in the first place speak of the several circumstances above enumerated as favouring the presumption of the guilt of the prisoner, and of the objections to which each is amenable, as either not established as a fact, or not warranting this inference; and afterwards state, in a summary manner, a few of the principal circumstances from which an opposite conclusion may be deduced.

And first, of those circumstances of the case which involve principally *medical facts*

and opinions, and which were presumed to substantiate the *corpus delicti*, or perpetration of the crime.

1st. The posture in which the corpse of Mrs. Reid was found at half past two o'clock, on Saturday, the 20th of September, 1834, the day of the supposed murder, was described by the witnesses Isobel Young, Mrs. Chisholm, Cherry Manners, and Mrs. Ness, to have been that of sitting on the floor by the side of the bed, with a portion of the bed-clothes round the lower part of the body, the face turned towards the bed, the head either inclined a little backwards (Chisholm), or backwards and to one side (Manners), or held erect (Ness), the left arm either resting on a chair (Young), or hanging down by her side, with the back of the hand on the ground (Chisholm), the right resting with the elbow on the bed, and maintained in the upright position without any further support, "as if she had been going to put it to her face," (Manners), and the legs crossed under the trunk, the left being less protruded than the right. This posture was presumed to be such as she could not of herself have assumed; and we find accordingly that it was the impression of Mrs. Chisholm and Cherry Manners that she had been placed in this posture by another person. But conceding that "the only way in which this posture can be accounted for," as stated by Professor Christison, "is the presumption that it had been changed," what, it may be asked, could be more natural than for Reid, on returning to his home, as he did at two o'clock, and finding his wife stretched perhaps upon the floor, to place her as erect as he could, and to wrap a portion of the bed-clothes around the lower parts of her naked body, before he went to seek assistance? Is it not what almost any man, in the same circumstances, would have instinctively done, and would his having done so afford any reason for believing that he had murdered the woman? On the contrary, would it not rather lead to an opposite belief, since, of all the postures he could possibly have selected, had he been a murderer, to make it appear that her death had been natural, the one above described was the least adapted for the purpose? We may concede then with perfect safety, if not with advantage, that the posture in which the corpse was found was that in which it had been placed by Reid. But it still remains a question whether this attitude were retained, as was supposed, by the rigidity of death; the occurrence of which would have warranted the presumption of Professor Christison that she had been dead some time, and perhaps therefore had been killed by Reid at his preceding visit to his house, which had taken place at nine o'clock, he having been absent from home from half-past nine o'clock till two. It is hardly necessary to say that the supervention of such rigidity by this time would have proved no-

thing prejudicial to the prisoner, since Mrs. Reid might have died from natural causes at any time during this interval: but the presumption is that no such rigidity had at this time taken place. At the time of Reid's changing the posture of the body, it had either already acquired this rigidity, or it had not. If it had, provided the woman had died in any other posture—and that she became rigid, as supposed by Professor Christison, with her limbs in this relative position while stretched on the bed or on the floor, is inconsistent, as remarked by Dr. Mackintosh, with the direction of the legs—he could not in all probability have made the body *assume* the attitude which it presented; if it had not, he could not, unless some other cause had been in operation, have made it *retain* that attitude. It may be said indeed that the upper parts of the body might have been already rigid while the lower were still flexible, and there can be no doubt that this is perfectly possible: but what right have those who take an unfavourable view of the question to assume, among so many other things, that such was the case, while they deny, as they do, to those who adopt the opposite opinion, the privilege of assuming any thing? Supposing however that Reid had either succeeded in bending the body, already stiff, into the attitude required, or, having placed it in this attitude while flexible, had held it stationary till it became rigid, how is this presumed rigidity compatible with the fact that, *at the time of finding the corpse it was perfectly supple*—so much so, that Mrs. Thomson thought that the woman had just died? The neck, we find, was so flexible as to allow of the head being immediately placed on a chair, as it was by Cherry Manners; the arms and legs were perfectly pliant, and “easily stretched down,” as they are described to have been by Mrs. Ness; and the whole body was so yielding as to admit of being directly laid out upon the floor, as is stated by Isobel Young, Mrs. Thomson, and other witnesses. It is true the rigidity of death ceases after some time, and, as observed by Professor Traill, may be diminished by much handling; but it never goes off so suddenly and so entirely, as to admit of a posture like the one described being thus abruptly changed. Further, the presumption that the retention of this posture was owing to rigidity is opposed to the fact that there was at this time no appearance of that discoloration which afterwards showed itself, and which, whether it depended on *ecchymosis*—in other words, the active deposition of blood by the blood-vessels while still possessed of vitality—or on *livor*—that is to say the passive deposition of blood by these vessels after the cessation of the circulation, but before the blood has become coagulated—would in all probability have manifested itself before such rigidity. It appears indeed in the highest degree inconsistent, as

observed by Dr. Mackintosh, to represent a dead process, like that of the supervention of rigidity, as preceding a living process, like that of the occurrence of *ecchymosis*; and if the rigidity of the muscles after death depend, as is probably the case, upon the same cause as the coagulation of the blood—namely the inspissation of the chemical principle called fibrin—it is reasonable to suppose that this rigidity would not have preceded *livor*, since the process by which the latter is effected implies that the blood is still in a liquid state: but to this subject I shall recur in future. I have said nothing of the partial warmth of the body when first found, since this is quite compatible with the occurrence of rigidity; but such is hardly the case with the want of the marks just alluded to. The fact appears to be, that while the erect posture of the trunk was the effect of the man's attempts to raise the corpse, the perpendicular direction of the right arm was the result, not of the ordinary *post mortem* rigidity, but of a spasmodic contraction of the muscles from a fit, in which the woman had died, not from two to eighteen hours, as supposed by Professor Christison, but probably only a few minutes before she was found; an accident to which—as will be shown in the sequel—she was obviously predisposed, to the exciting causes of which she had been recently exposed, and the supervention of which about this time might, from the immediately preceding symptoms, have been anticipated. The probability is, that on getting out of bed—and she seldom rose, as we learn from Isobel Young, till past mid-day, she had fallen on the floor in a convulsion fit, and that the effects of this, after death, were more perceptible on the right arm than on the left, because the right side of the body was comparatively healthy, and therefore more susceptible of spasmodic action, while the left was palsied. Of this palsy and its effects I shall have to speak elsewhere, but in the meantime I may remark that it was the right side of the head principally, according to Cherry Manners, of which Mrs. Reid was accustomed to complain, as is frequently the case in palsy of the left side of the body; and towards the right side, according to Mrs. Fife, that she inclined during walking*, as would probably be the case from the greater action of the muscles of the spine on this side than on the other having produced a curvature of the spine in that direction. And these facts, while they favour the presumption that the peculiar

* Mrs. Gray or Smith of Kirkaldy says, that it was towards the *left* side that Mrs. Reid inclined; but it is fair to believe that Mrs. Fife, her immediate neighbour, was less likely to be mistaken in this particular than Mrs. Smith, who lived at a distance, saw her but seldom, and was not acquainted with her.

posture in which the limbs were found depended upon a spasmodic contraction of the muscles, are further hostile to the notion that it was maintained by the rigidity of death; such rigidity occurring not less remarkably—perhaps even more remarkably—in palsied limbs than in those which are healthy. The former presumption likewise is quite reconcileable, while the latter is not, with the sudden and perfect return of flexibility. Again, Mrs. Reid had suffered, only a short time before, an attack of apparently precisely the same kind, in which, as appears from the evidence of Young, Thomson and others, she became speechless and seemed to be dead; the body was cold, and the “*arms so stiff*,” that Mrs. Thomson had “*great difficulty in getting on her shift*.” Was this the stiffness of ordinary *post mortem* rigidity, or that of spasmodic contraction? How long the stiffness from the latter cause may continue after apparent death I shall not here stop to inquire. We know that the features of the face often retain, till putrefaction supervenes, the expression of the last mental emotion; that in cases of death from cholera the contractions of the extremities are often equally permanent; and that after death from tetanus, particularly as induced by certain poisons, the permanence of such contractions is still more remarkable: but upon this subject I have no intention of dilating. It is sufficient for my immediate purpose if it be conceded that they may continue for only a few minutes, so as to obviate for this period the natural tendency of gravity; for that the woman had not been dead any great length of time is presumable, among many other things, from the non-appearance at the time the corpse was found, or *for a long time afterwards*, of the least degree of *livor*, a fact which Professor Christison himself admits is irreconcilable with the opinion that she had been killed at nine o'clock. If this be true she must have died at some time between half past nine o'clock in the morning, and two in the afternoon, during the whole of which time Reid was out of the house, and therefore could not have killed her. For the presumption, supported by Dr. Forbes, that the fatal blow might have been inflicted at nine o'clock in the morning, or even at twelve o'clock the preceding night—when the exclamation already alluded to was heard—and not produce its effect till some hours afterwards, when, upon the woman's attempting to raise her head, the supposed injury of the spine was made to bear upon the spinal cord, is obviously untenable; since a blow of sufficient violence to produce this injury of the spine must, as admitted by Professor Christison, have at once proved fatal, if not by the direct physical compression of the spinal cord, at any rate by the intensity of the concussion to which it must have been subjected. It would have settled the question respecting

the presumed change of posture after death had the natural *livor* displayed itself by the time the body was found; since it would of course have been seen principally, not in those parts which were undermost at this time, but in those which had been undermost while this process was going on: but this criterion was of course unavailable in the present instance. Whether the posture were changed or not however, the circumstance furnishes, as I before observed, not a tittle of evidence in favour of the presumption of murder, except as taken in conjunction with Reid's denial, at one time, of having been at home at two o'clock, of which I still have occasion to speak under the head of the moral circumstances of the case.

To be continued.)

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS, FROM BIRTH TO PUBERTY.

BY DR. RYAN.

*Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE XLVII.

Lientery—Watery Diarrhoea—Watery Gripes—Prolapsus Recti—Cholera Infantum—Inversion—Natural History of Intestinal Worms—Are Worms generated within or without the Animal Body?

GENTLEMEN—We have now to consider the remainder of the diseases of the intestinal canal, so as to complete the pathology of this part of the human body. The subjects which claim attention during this lecture are that form of diarrhoea termed *lientery*, *prolapsus recti*, *cholera of infants*, and the *natural history of intestinal worms*.

The last kind of diarrhoea which demands notice is that termed diarrhoea *lienteria*, in which the food passes through the bowels slightly digested or nearly unchanged.

Lienteria—Watery Diarrhoea—Watery Gripes—The motions in this disease are thin, watery, and copious, often astonishingly abundant; they are white and mixed with half-digested food, which is passed before the chyle is absorbed; and every thing the infant takes “*runs almost immediately through it*.” In a few hours it is often reduced to the lowest condition, and frequently dies within twenty-four or forty-eight hours, unless proper means are employed for its relief. The stools may or may not be tinged with bile.

The proximate cause of the disease is subacute inflammation of the intestinal mucous membrane. There are no colics or severe gripings unless the mucous membrane of the intestine is congested, inflamed, or ulcerated.

It was formerly supposed that lientery was caused by atony or want of tone in the stomach; but dissection has disproved that pathology. Indeed, it would be difficult for a modern pathologist to understand how several motions, for example, twenty or thirty, could be suddenly expelled from the intestinal canal in a state of atony, though such rapid expulsion would be better explained by referring it to inordinate peristaltic action, excited by irritation or inflammation.

M. Capuron states that the uniform white colour of the dejections distinguishes them from mucous and serous evacuations; and Dr. Good asserts that the secretion of bile is arrested in this disease, or very rarely appears. Dr. Dewees, on the contrary, informs us that this is not the case, and that the motions are often mixed with bile. The diagnosis between this disease and severe purging, described by Dr. Underwood, is so very confused, that I do not pretend to understand it.

As the aliments remain but a short time in the stomach and bowels, and are not digested or converted into chyle, and as there is not nutrition or new material for blood added to the circulation of the vital fluid, emaciation, marasmus, and hectic fever, speedily appear.

If the disease do not depend on inflammation, but on atony, it may be cured.

The *treatment* already recommended for diarrhœa should be rapidly employed, and if there be great exhaustion, aromatic spirit of ammonia, or the succinated spirit in syrup, arrow-root, or some beef tea, chicken broth, or animal or vegetable jelly, will be of essential service in rousing the vital power. A mild nourishing diet, such as already advised in diarrhœa, with tonics, chalybeates, &c., will be necessary after the lientery is checked, to improve the appetite and general health.

Dr. Underwood strongly recommended emetics of antimonial or ipecacuanha wine; but these are now seldom employed. I have stated the objections to these medicines in a former lecture, when describing erythematic and follicular enteritis.

Every one of the forms of diarrhœa now described may become chronic, and continue for weeks or even months, more especially at the period of ablatation or weaning, on account of the improper diet usually, indeed generally exhibited at this time. Diarrhœa is also obstinate and chronic at the periods of teething and weaning. Dr. Cheyne has written an essay on the atrophica ablatatorum, or "weaning brash," or diarrhœa at this period, in which he concludes that the disease is caused by acrid bile, or rather the morbid state of the liver, that occasions it. According to my experience and observation, the diarrhœa caused by weaning differs in no respect from the forms I have already described, and which may occur at any period of infancy; and the same treatment, with certain modifications, may be used in all the forms of this disease.

When diarrhœa is severe or chronic, it may

be followed by protrusion or displacement of the rectum—a disease whose pathology I described under the head of displacement of organs. I shall now content myself with recapitulating its more prominent characters and treatment.

Prolapsus Ani—Prolapsus Recti—Procidencia Ani—Descent or falling of the Lower Bowel.—Descent or falling of the lower bowel is often caused by diarrhœa, more especially if accompanied by much tenesmus, or of frequent forcing attempts to go to stool, as under such circumstances the bowel is relaxed, and disposed to protrude. It should be recollected that the internal or mucous coat of the lower bowel possesses numerous folds, and it is this that is most commonly protruded. When its surface is irritated by worms, or when a costive infant makes repeated efforts to evacuate its bowels, or when drastic purgatives are given, or when there is diarrhœa, constipation, or stone in the bladder, any one of these diseases may cause tenesmus and descent of the inner coat of the bowel. This forms a red, soft tumour, which is not painful at first, but will speedily beset, if pressed on or strangulated by the sphincter, or the circular muscle, whose use is to close the extremity of the bowel. In this last case the protruded part may readily inflame or mortify.

It is therefore necessary to ascertain the cause of the protrusion, to remove it speedily, so as to prevent danger. As soon as the cause is removed, the disease is rapidly cured.

Treatment.—In cases of simple relaxation there is little or no difficulty in returning the mucous lining of the bowel, or the bowel itself. The protruded part should be fomented with warm water, or a decoction of chamomile or poppyheads, and great care must be taken not to apply the fomentation, or as some term it the stupe, too hot, lest it inflame the bowel. I have known an instance in which inflammation was excited by making a child sit on a warm brick rolled in flannel—a popular and sometimes a piece of medical practice. Some practitioners advise, to place the patient, whether an infant or adult, sitting over a vessel containing warm water, before any attempt is made to return the protruded part. Others recommend the use of warm astringent fomentations, such as decoction of oak bark, simple infusion of roses, without sulphuric acid, or the application of warm port wine, and the vapour of turpentine arising from throwing this medicine on a red iron.

It appears to me that the application of astringents, while the bowel or its membrane is protruded, is sometimes useless. The application of cold or vegeto water, with a few drops of laudanum, will sufficiently contract the part, and facilitate its return. Warm fomentations will relieve irritation and pain, and tend to produce the same effect. When these remedies are employed, we should next compress the tumour between the finger and

thumb, and, with the forefinger smeared with lard, olive oil, pomatum, or spermaceti ointment, push the part into its usual situation. It would be then advisable to use a starch and opiate clyster, a decoction of oak bark, or infusion of roses with opium, or to apply cold to the anus for a few minutes, then a compress secured by a roller or bandage passed between the thighs, and also round the abdomen. The exhibition of a proper dose of opium or other sedative by the mouth is also advisable, as the action of this on the stomach will be conveyed sympathetically to the affected portion of the digestive canal, and abate any degree of pain or irritation in that part. It is scarcely necessary to observe to the regularly educated medical practitioner, that the whole tube from the mouth to the anus is continuous, and forms the digestive, alimentary, or intestinal canal, and that irritation in any part of it may affect the whole, and that a sedative applied to any part of it, will relieve irritation in any portion of it, however distant. Many proofs of the correctness of this statement might be adduced, but one or two shall suffice. Who does not know that teething will cause bowel complaint; that worms in the lower bowel will irritate the mouth and nostrils; or that irritation, inflammation, ulceration, worms, or undigested food in any part of the tube, from the stomach to the anus, will not only derange the whole or any part of the alimentary canal, but cause convulsions, by irritating the brain as well as all parts of the body? On the same principle, a sedative taken into the stomach or rectum will relieve any one or the whole of the derangements mentioned. The greatest care, however, is necessary in regulating the dose of this valuable remedy, when it is given by the mouth and rectum, as an overdose may cause fatal effects. The quantities already mentioned in these lectures may be prescribed to act on the stomach or rectum, but non-professional persons should not venture on the use of sedatives or soothing medicines in both ways. If they do, they will, in a preponderating majority of cases, poison the patient. It sometimes happens that the protruded part, both in infants and grown persons, becomes intensely red, black, and painful, and cannot be reduced or returned. This state is caused by the pressure of the sphincter ani, and requires the free application of the cold lotion already advised, which according to Underwood is generally effectual, though according to his commentator, Dr. Merriman, leeches are sometimes necessary. My own experience accords with that of the latter writer: suppositories, tampons, or plugs, wetted with the astringent decoctions already enumerated, have also been advised, and these are decidedly useful in obstinate cases. Astringent clysters with or without opium are also highly beneficial to prevent the redescend of the bowel.

In fine, descent of the lower bowel, or of its lining membrane, is scarcely ever fatal to infants or grown persons. The remedies proposed will generally remove and prevent it. The internal and local use of sedatives is also highly beneficial. All irritation in the alimentary canal or contiguous organs should be removed, and the general health restored by tonics, mercurials, proper diet, &c. The daily application of cold water, or other cold lotions to the anus, is also a valuable preventive. The use of the bidet, or the injection of cold water into the bowel, once or twice a day, is highly beneficial to grown persons, who are liable to this, or indeed any other diseases of the rectum.

Cholera Infantum—Cholera of Infants.—This is a rare disease in children under five years of age in this country, though common in the United States of America. We sometimes observe children affected with vomiting and purging of bilious matter, but most commonly there is more or less fæces in the motions. It was very remarkable, that malignant or blue cholera scarcely ever affected infants at the breast of a mother dying of the disease, or very young children. The indications of *treatment* are to correct the acrid state of the bile or other matters, by copious tepid diluents, barley water, beef or chicken tea, and to allay the irritation in the stomach and intestines, by opiates and astringents, as the mixtures mentioned for the treatment of vomiting, acidity in the stomach, and diarrhoea. Opium may be given by the mouth, in clysters, or applied externally by friction on the abdomen. The saline draught with opium, given in the act of effervescence, is also useful to allay the vomiting.

The tone of the stomach and bowels should afterwards be improved by tonics and alterative doses of mercury; such is the plan of treating simple cholera in children as well as adults. The simple cholera of this country was in general rarely fatal until the appearance of the malignant disease in 1832, but since that period we observe cases that destroy life in fourteen or sixteen hours.

Invermination—Worms—Natural History of Worms—Are they formed within or without the Animal Body?—It is a singular fact that we have not in our language a good account of the natural history of intestinal worms, nor even in all that has been written by helminthologists. I shall therefore attempt an outline of such in the following remarks. Naturalists and physiologists have never agreed on the origin of worms in the human body. Hippocrates, Galen, and the ancients, attributed these troublesome inhabitants of the digestive and other organs, to a putrefaction of the humours. Selle, Grimaud, Muller, and many others, concluded that they were formed by a vital principle in the intestinal mucosity. Others supposed them to be spontaneously generated; and some considered that

pre-existent germs were developed, as Rhæder, Wagler, Swammerdam, Valisnieri, Reaumur, &c.

A question then arises, do the germs enter with the food or drink, or with the air, into the lungs, or are they transmitted by fathers and mothers at the time of generation, as maintained by Andry, Leclerc, Bloch, &c.?

It would occupy too much time to enter fully on the consideration of the origin of worms at present, but I shall notice the leading arguments on the subject: I agree with Van Swieten in thinking, that it is sufficient for a medical practitioner to recognize the symptoms and remove their cause. Worms have been found in different parts of the body unconnected with the digestive canal. Duverney describes the case of a child five years of age, who complained of acute pain at the root of the nose; it suffered from slow fever for three months, when it expired in severe convulsions. On opening the head, a lumbricus about five inches in length was found in the longitudinal sinus, which remained alive from six o'clock in the morning to three in the afternoon. Baglivi relates another singular case: the patient was a man aged forty years, who suffered from violent pains in the stomach, day and night; he complained every quarter of an hour of slight transient convulsions, his countenance was pale, his strength depressed, and after having suffered severe agony for eight days, he enjoyed a calm for two hours. At the expiration of this time he was seized with violent pains in the stomach and chest, which were speedily followed by death. Before the sufferer died, he complained of a sensation as if his heart and stomach were gnawed by dogs. On opening the body, there was found in the pericardium a blackish worm, alive and vigorous, covered with hairs, about the breadth of the hand and four fingers. The heart was of a livid colour. Again, worms have been found in the eye, in the antrum, in the ear, in the chest, lungs, liver, blood, &c. &c. No one, however, as yet, has given a satisfactory, or even a plausible explanation of these astonishing phenomena. Worms have also been found in the bowels of the fœtus in the womb, and hydatids have been discovered in every organ and tissue in the body. It is also to be remembered that every species of animals has its particular worms—birds, fishes, quadrupeds, and man. Shall we conclude then with Swammerdam, that the generation of worms in the bodies of animated beings, is a mystery which reason cannot penetrate?

Worms are observed in the different parts connected with the outlets of the body; they have not only been discovered in every portion of the digestive tube, the small and large intestines, the stomach, œsophagus, mouth, nostrils, eyes, ear, urethra, and vagina, but also in the substance of solid parts, and even in the blood and other fluids.

It is also a singular fact that there are different species of worms in different organs. This is constantly observed in the different portions of the intestinal tube, and occasionally in other parts of the body. Proofs of this statement will fully appear by the sequel.

Besides intestinal worms, there are others that infest the skin, as the *acarus scabiei*, *œstrus*, *filaria*, or *dracunculus* and *gordius*. We shall, however, confine ourselves to the description of the intestinal worms.

Vermes Entozoa—Entozoa—Vermes Intestini—Helmenthi—Helmenthia Alci—Helmenthia Podicis—Intestinal Worms.—These, according to Cuvier, form the medium between the class of worms and that of zoophytes. They do not appear to possess cartilages or blood-vessels, and some seem to have muscles, generative organs, and a nervous system composed of ganglions, while others are devoid of it. They are found not only in all the cavities, but in the tissue of organs. Various naturalists, among whom were Cuvier, Bloch, Brera, Bresmer, Laennec, and others, have endeavoured to class them, some according to their shape, others according to their anatomical characters.

The chief entozoa that infest the human body are, the *filaria medinensis*, *trichocephalus dispar*, *oxyuris vermicularis*, *ascaris lumbricoides*, *strongylus gigas*, *distoma hepaticum*, *bothriocephalus latus*, and *tœnia solium*, all which have vision. The commonest of these are the oxyures vermiculares, ascariides, lumbricoides, and tœnia.

The organization of worms varies from the lowest degree, in which we can scarcely discover any trace, as in the tape worm, which appears at first as a cellulo-gelatinous mass, until we arrive at a higher state of organization, in which we find muscles, organs, sexual apparatuses, and according to some helminthologists, a tolerably perfect nervous system.

Much discrepancy of opinion exists as to the origin of human intestinal and other worms. Some contend that they are generated within the body, others that they are conveyed into the body in the food or drink, or air during respiration.

It is urged on the one side, that the more common species, as the tape, round, and thread worms, have never been found living external to the body; and Bresmer urges, that if they were conveyed from without, we ought to find them more abundant in the earth, water, &c.; but the contrary is the fact.

Linnaeus stated that he had observed the tape and thread worms in a marsh in Lapland; but Muller has since proved that the worms he described are never found in animals. There are, however, abundant facts to prove that the ova of insects are taken into the system; a few of which I shall mention, and refer you to Good's Study of Medicine for numerous others.

Invermiration—Worms or Larvæ of Insects inhabiting the Human Stomach or Intestines.—Physiologists have at different times referred nearly all human diseases to vermination as their origin. Thus, Linnæus maintained that dysentery is the effect of a peculiar larva or grub belonging to the acarus or tick genus, which he has called *A. dysentericæ*. Kircher has ascribed the plague to another kind of animalcule; Langius, the measles; various authors, the itch; Sigler, petechiæ, Lusitanus and Poncillus, the small-pox; De Sault, hydrophobia; Hauptman, syphilis; Martin and Udman, pupils of Linnæus, elephantiasis; Nyander, another pupil, most, if not all contagious diseases; some said this was the cause of piles, of the black spots on the forehead, called acne; and others, the toothach. We also observe the extensive use made of the *tænia hydatidis*, which is said to be the parent of every limpid cyst, of tubercles in the lungs, of cancer; and even the most enlightened physiologist supposed man himself in every instance is the progeny of the same kind of maggot, and that this might be seen by any one who took the pains to look for it, vivaciously frolicking in the vast ocean of a drop of male semen. Such is the glorious uncertainty of medicine. We have at length approached to more correctness in our observations, and are more sceptical in our conclusions. It has been long known that incipient putrefaction, or a quiescence and exposure of animal fluids to warm atmosphere, will load them with animalcules; and these are maintained by some of our profession to be the result of equivocal generation. The most opposite and varied form of animal will be produced; and if equivocal generation were the cause, then man and all animals ought to be produced in the same manner. Aristotle was right after all, when he said, "*ex nihilo nihil fit*"—these productions are not generated from nothing. Natural history and genuine science afford a solution of this fallacious and generally received opinion. The atmosphere is swarmed with myriads of invisible ovula, and which are deposited in putrefying fluids which give out heat, and thus form a proper nidus for their evolution. These insect eggs in the air, elude our senses, and yet their existence must be obvious to any one who will condescend to observe what is termed, in vernacular language, a blight upon plants and gardens. Thus, a hop ground will be destroyed in twelve hours after a honey dew, by the *aphis humuli* or hop green-louse. This dew or mist is loaded with the eggs of the animal, and it stimulates the hop leaves to secrete a saccharine and viscid juice, which destroys the young shoots by exhaustion, forms a favourable resort for the insect, and a cherishing nidus of little dots, which are eggs. These are hatched in forty-eight hours, and are succeeded by hosts of other eggs of the same

kind, and these breed viviparously in both ways. Now it is probable, indeed certain that there are myriads of myriads of ova of various sorts in the atmosphere, which are deposited in situations favourable for their evolution. Even distilled water is not freed from them; and this is admitted by many naturalists, who placed the fluid in a marble basin, and found its surface in a short time loaded with various species of confervas, while the interior was peopled with microscopic animalcules. Again, damp cellars are covered with various funguses, and the driest brick walls are often lined, and their tops covered with lichens and mosses.

It is said that animalcules were found in abscesses; but admitting this for the sake of argument, and there is no respectable authority for the narration, their respective ova were taken in with the food or air, and separated as soon as they acquired a proper nursery or nidus. Several species of these animalcular eggs are often hatched in other substances than animals. Rolander saw the dysenteric worm of Linnæus in a water vessel made of juniper wood, and maintained it was from drinking the water that he was attacked with it. Dr. Barry of Cork describes a family all of whom were attacked with the same kind of worm, and one of them observed it in the bottom of a well from which they had water. (Trans. Dub. Coll. Phys. v. 2). Lister saw the *ascaris vermicularis*, the common mawworm, infesting the surface of a well; Linnæus the *tænia solium* or tapeworm in a muddy spring, and Palmærus has proved that the fluke or *fasciola hepatica*, which infests the liver of sheep, exists in marshes and stagnant waters. One of the most extraordinary cases of this kind on record, occurred in Cork in 1822—which I shall read for you hereafter—in which beetles or clocks were found alive in the living stomach. Any one acquainted with natural history, is aware how the same species assumes so different an appearance in different stages of its existence. For example, the caterpillar and the gaudy butterfly, the caterpillar and winged moth; the tadpole with gills and fish tail, without legs, becoming the legged frog without gills or tail. I might multiply examples, and introduce this fact, as it bears strongly on the danger of insects in the human intestines. We are however unacquainted with the history of thousands of thousands of these ova; nor perhaps could we know the whole history of *ascarides*, *lumbrici*, or *tænia*; and hence we may not know them out of the body, even though we should meet with them under some form or other. As animalcules are parasitic to plants, so are plants to animals. Thus, we know that in one night the sheets of patients with gangrenous limbs, when the discharge has soaked, will be covered with funguses; in fact there is no vegetable that is not infested by the parasitic plunderers, nor no animal,

from the highest to the lowest, that is not a prey to other animals of a minuter form, which infest its interior as well as its exterior.

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from page 63.)

Treatment of Stricture.

"6th. A dilator for widening the stricture after a small instrument can be passed through it; it is intended as a substitute for the bougies and sounds of former times.

"The chief objections to these instruments are, the painful friction, the danger of making false passages, the tediousness and imperfection of the cure, and that they cannot dilate any part of the canal beyond the size of its orifice, which, during health, is the narrowest part of it.

"The dilator consists of a tube of thin membrane introduced empty into the stricture, on a pointed wire, and then filled with fluid by a syringe, so as to dilate with any degree of force, from the mere filling of the part to the strain of the hydrostatic press, which will tear the strongest texture that disease can form.

"The dilating tube is about two inches long, and its near end is fixed to the point of a small catheter, through which the distending fluid is injected.

"The tube is formed of thin silk ribbon, of various sizes, with the edges joined.

"It is lined with prepared gut of the cat or dog, which is almost as thin as gold beaters' skin, although very strong and water-tight; and it is covered with the same, to give the smoothest and softest possible external surface.

"When complete, and enclosing the blunt wire, it is less bulky than the bougie which would be required for the same case.

"Thus it passes easily; it cannot tear the canal, or make false passages; it can enter through a small orifice, and dilate beyond to any desired extent; and its greatest advantage is, that by opening, so as to follow the yielding of the stricture, it can effect, at one application, what only a succession of hard bougies, with long treatment, could accomplish.

"In one day it has often removed disease, which had resisted other means for months and even years.

"Some practitioners and critics, not understanding the law of fluid pressure (explained at p. 229), objected at first to the dilator, that a little water or air pressed into it by a syringe would be unable to overcome much resistance.

"Had they seen the instrument lifting so readily as it does a heavy weight laid upon it, or snapping a strong ligature tied round it, they would not have had the prejudice.

"It was objected, also, that the instru-

ment would do mischief in urethral disease by dilating the canal before and behind the stricture, more than the stricture itself; now its dimensions being fixed, owing to its silken tunic, it never can distend beyond the diameter chosen; and, therefore, if of the proper size, it can only press on the stricture itself.

"It was also said, that this instrument requires, in the operator, greater manual dexterity and acquaintance with mechanical philosophy than many surgeons possess; but this is merely saying, that the arts are progressive, and that the accomplished surgeon, at the present day, is more dexterous and intelligent than his predecessors of a century ago.

"It is no reason why the delicate apparatus of the oculist should fall into disuse, that all surgeons are not able to apply it.

"Some attempts had before been made to construct a dilator of fluid pressure, but they produced nothing of value.

"For urethral purposes, a simple gut, or intestine, is worse than useless; for, being yielding in its texture, the surgeon can never know truly the size of his instrument, and, therefore, may do much mischief with it.

"Dr. Ducamp, in speaking of the dilator, allows that he did not first invent it; but then, from ignorance of what constitutes its true value, he takes praise to himself for simplifying and improving it, by throwing away the silk, and using the gut only. A variety of metallic dilators have been contrived, and used by English surgeons, since the publication of Dr. Arnott's Treatise on Strictures; but, although manageable with less trouble than the fluid dilator, they want its chief merits.

"The dilator is applicable to many other purposes, in surgery, besides that now mentioned: as for removing stricture of the gullet, or of the rectum, for checking hemorrhage in deep wounds, for dilating wounds, as a tent, &c.

"The operation of lithotomy was saved to a gentleman whom Sir Astley Cooper and the author were attending together, by the dilator opening a fistula in perineo, so that a large stone was extracted without cutting.

"The dilator has also served for opening the way for stones from the bladder.

"7th. Another improved means for the treatment of stricture, described in the Treatise, is a mode so as not to touch any other part of the canal.

"Formerly, the caustic was applied to the face of the stricture, and therefore had almost always to destroy a portion of the healthy canal before it could reach the contracted fibres; the extent of such portion depending on the distance from the contracted fibres to the part where the lining of the canal began to be drawn inwards by them.

"This explains why not unfrequently a hundred applications of caustic were made; a single application generally suffices.

"To accomplish this, a ring of caustic is placed (as described in the Treatise) on a bougie of a peculiar construction, about an inch from its extremity, and the bougie being then passed down to the stricture, through a tube or conductor, the point passes beyond the stricture, and carries the caustic to the very spot where it is desired to act."

The instruments of Ducamp, Lallemand, and Phillips, are modifications of Arnott's, and their mode of application may be seen by referring to the plates and letter-press description to be given in our next number.

It must be obvious to every practical surgeon, that they are infinitely superior to the unsafe caustic bougie of Sir Everard Home, which cauterizes the whole urethra, causes intolerable pain, spasm, hæmorrhage, and often inflammation of the bladder, perinæum, testes, &c. In some cases the spasm of the urethra dislodged the caustic, and it was necessary to cut down on it to extract it.

There are four methods in use for the cure of permanent stricture:—1. Gradual dilatation by bougies; 2. Forceful dilatation by sounds; 3. Cauterization; and, 4. Incision.

The profession is very much divided in favour of these remedies. British surgeons prefer dilatation; the French, and most other foreigners, cauterization. It is an axiom in this kingdom, that caustic should not be tried until dilatation has failed. Others maintain, that the treatment by dilatation with bougies, however well applied, is long, painful, and almost always palliative. The effects of bougies are three: to dilate, compress, and irritate. Catgut bougies were supposed to produce the first effect. When they were introduced into the urethra, they swelled, after having absorbed the moisture of the canal, and, consequently, they dilated or compressed the stricture. These are now generally abandoned.

Metallic bougies are generally preferred, because they enable the operator to make efficient pressure. Some recommend leaden bougies, others silver. Gum elastic bougies are not generally employed in this country, though they are useful in certain cases. All instruments of this sort, of whatever material, cause irritation, and more or less discharge of mucus. Caustic bougies ought, therefore, to be preferred, if this was a desirable object.

Sir A. Cooper, who is a strong advocate of metallic instruments, uses a conical silver one, and introduces two each day, one immediately after the other, the one being smaller than the other, and those employed the next day are still larger. He continues this plan daily, until he can pass an instru-

ment of No. 14. He first passes a wax bougie, warmed by the fire, for the purpose of ascertaining the seat and form of the stricture. By the daily use of two bougies, the size being increased, he states that stricture can be cured in less than a third of the time that it usually is. He says that it is not necessary to leave the bougie passed for any length of time. He condemns straight instruments. He is also opposed to caustic or armed bougies, unless when there is fistula in perineo, as otherwise they might cause retention of urine. He observes that the caustic alkali is more soluble than the nitrate of silver, and consequently more likely to do mischief.

The introduction of bougies is a much more delicate and difficult operation than is generally supposed. The best mode of performing the operation is as follows:—The patient is placed standing before the surgeon, who seizes the penis behind the glans, between the thumb, index, and middle fingers of the left hand, while he introduces the oiled bougie with the right hand. The penis should not be raised towards the abdomen, but extended horizontally, so as to render the urethra as straight as possible, and to efface its lacunæ or valvular-like folds. The bougie is then gently and cautiously introduced along the canal, it being turned between the fingers, until it encounters some obstruction. When its passage is arrested, we can easily distinguish whether the point of the instrument has passed the stricture, or is in front of it. In the latter case, the instrument should be withdrawn a little, then re-passed to the obstacle, and this plan repeated until the point has fairly come in contact with the stricture.

When the point of the instrument has arrived under the pubes, we should depress the penis so as to diminish the curvature of the urethra. We will facilitate its passage by pressing on its point, through the perineum, and directing it towards the neck of the bladder. When the obstacle to its passage is still further on, it will be advisable to introduce a finger into the rectum, for the purpose of guiding the instrument through that portion of the canal in which it is arrested. When the obstruction is within five inches of the orifice of the urethra, a straight instrument may be employed, but when near the neck of the bladder it may be necessary to bend the bougie to the curvature of a catheter. Sir A. Cooper holds, that in all cases the instrument ought to be curved, as otherwise its passage will be arrested, even in a healthy urethra, while Civiale, Costello, and Heurtaloup pass straight instruments with as much ease as curved ones.

The curve is immaterial, according to Macilwain, when the instrument is flexible. Mr. Stanley has well observed, that according to the natural course of the urethra, as indicated by dissection, the part of the ca-

theter or sound corresponding to the curve of the canal under the pubes should form a considerable segment of a circle, about $1\frac{1}{2}$ or 2 inches in diameter, and the remainder of the instrument may be perfectly straight*. Professor Cooper recommends wax or flexible metallic instruments as safest. The instrument should be as large as the stricture will permit, as every surgeon knows that one of a small size is passed with difficulty, and is likely to pass into the lacunæ of the urethra. Sir A. Cooper recommends a silver bougie or catheter; Mr. Macilwain the latter; while numerous surgeons of eminence employ instruments composed of zinc and pewter, which are flexible, and may be readily bent to any curve. Sir B. Brodie condemns leaden bougies, on the grounds that they might break in the urethra or bladder, and prefers gum elastic. Nevertheless, metallic bougies are most generally employed at present.

In all cases, we should proceed with great care and gentleness, as few can bear the introduction of a bougie for the first time, or when the urethra is irritable, without suffering some pain or uneasiness, and sometimes even fainting, rigors, cold sweats, &c. Mr. Hunter described a case in which the patient could not after several weeks bear the instrument longer than eight or ten minutes at a time. The instrument cannot be borne longer than a minute or two by some persons; but by its frequent use, it may be worn for a period from a quarter of an hour to two hours. Some use it twice or thrice a week, others employ it daily. When the instrument is allowed to remain for an hour or two, it should be secured round the penis and loins. When we pass the stricture, we ought to be cautious in advancing the instrument towards the bladder, because the portion of the urethra between the obstacle and neck of the bladder is generally irritated or inflamed, and the presence of the instrument will excite pain, which will extend to the prostate, bladder, kidneys, &c., excite the sphincter, and close the neck of the bladder, and cause retention of urine. When the stricture is so dilated as to admit a large bougie, we should be careful not to dilate the canal behind it, unless this be necessary, which is seldom the case. The belled bougie, proposed by Ducamp, will only dilate the strictured part, and not the portions of the canal anterior or posterior to it. This is an evident advantage. Whatever may be the form of the stricture, whether it exist in one or many points, or in the whole circumference of the urethra, the pressure of the increased size bougie will widen the canal, compress its parietes, and flatten their projections. Delpech passed a catgut bougie in some cases, allowed it to remain for two hours, removed it, and introduced a

large one*. But it may require a long time, from one to twelve months, to effect a cure by dilatation†. The patient, as well as the practitioner, must have patience. In some cases, great pain is produced, which may cause retention of urine, inflammation of the testicles, and, if the instrument be passed in a wrong direction, it will make false passages, which may cause urinary abscesses, fistulæ in perineo, and inflammation of the prostate gland. Few persons will submit to such long treatment. In some instances the instrument must be worn day and night, the patient is obliged to withdraw it to void his urine, and very often may not be able to re-introduce it, or may suffer from want of sleep on account of the irritation it produces. The irritation caused by bougies, in all cases, may be followed by inflammation and stricture, by the very disease for whose removal they are employed. Many also consider that these instruments predispose to the re-appearance of stricture. M. Ducamp maintains, first, that "this treatment is uncertain and often impracticable; second, that it is painful and very tedious; third, that it is never more than palliative." His predecessor, M. Cho-part, graphically points out the difficulties and dangers incidental to this method of cure‡.

It often happens that after one stricture has been dilated, we discover another further on, which will require a smaller instrument than we have lately used; and then the pressure being removed from the first, a relapse may speedily take place. It therefore appears, in such a case, that we must be always commencing this plan of treatment. Again, we may excite an urgent desire to pass urine, or a pain at the neck of the bladder, which may continue for hours or days. Frequent and painful erections, dysuria, pain extending from the bladder to the vesiculæ seminales, thence to the vasa deferentia, testicles and inguinal glands, are often induced by bougies. Finally, the stricture generally returns in a year or two, and this fact has led Stoll and others to reject bougies and sounds altogether.

This conclusion, however, is invalid, because the relief afforded for the time specified is much better than no relief at all, or than all the misery which would be endured without them. Hunter, Sæmmering, and Boyer, consider dilatation an uncertain and palliative treatment only.

Treatment by Sounds or Catheters.—Sounds have been used in the treatment of strictures from an early period. Those of the Romans, as described by Celsus, b. vii, c. 26,

* Clinique de Chir.

† Richerand Nosographie Chirurg. t. iii, p. 507.

‡ Traite des Maladies des Voies Urinaires.

* Macilwain on Strictures, &c.

were made of copper, and varied from 9 to 15 inches in length. Some of these had two curves, and resembled those invented, at a more recent period, by J. L. Petit. This surgeon proposed an instrument shaped like an *S*, as he frequently observed a sound with one curve, when left in the bladder, caused inflammation and ulceration. This instrument was at length superseded by the gum elastic catheters. Various compositions were proposed for sounds previously to the use of gum elastic. Van Helmont proposed a copper wire covered with glue*, Fabricius Abaquapendente one of horn, and Tolet described one of silver wire made spirally†. Macquer proposed caoutchouc, or gum elastic‡.

Sir E. Home made many experiments to discover a method by which elastic sounds might be brought to a fixed curve. The object of using sounds is to pass them into the bladder and force them through any obstacle that might exist in the urethra. Every one acquainted with the structure of the urethra must at once admit that forcing a sound or catheter through a stricture is a most dangerous operation, may cause false passages, perforate the bladder, prostate, or rectum, and do irreparable mischief. The experienced surgeon is well aware that catheterism is often one of the most difficult operations he has to perform. The urethra under the pubis is differently curved in different persons, on account of the width or closeness of the arch of the pubes. Hence the necessity of the different curves of catheters. The curvature of the urethra also varies in each individual, according as the bladder is more or less distended, or the prostate enlarged. The diameter of the urethra is about four lines, on the centre of which the beak or point of the instrument is to pass, and, if force be used, the parietes of the canal may be readily perforated, and a false passage made. This may also happen when the lacunæ are large, or the stricture is indurated. The danger would of course be increased when, instead of one, there are two or three obstacles. We must, therefore, I think, fairly conclude that forced catheterism is a most hazardous operation. Even Dessault perforated the rectum§. Chopart, Ducamp, Sir C. Bell, and a host of others, described false passages and other serious injuries caused by catheterism.

I have already stated, in describing the treatment by bougies, that the presence of a foreign body in the urethra excites irritation and inflammation, which oblige us very frequently to discontinue that plan of treat-

ment. But inflammation was always more intense in the treatment by sounds or catheters, as these used to be left in the urethra for twenty-four hours at a time, while the bougies were only left a few instants. The consequence was that one or more points of the canal became irritated, and the contact of a hard substance predisposed it to inflammation, and this last disease was preceded by acute pains, pain and difficulty in voiding urine, and, finally, swelling of the penis. It then became necessary to remove the instrument, to recommend repose, fomentations, baths, cataplasms, leeches, &c. In a great number of cases inflammation of the testicle and inguinal glands followed. These may be also induced by bougies, as already stated, but more frequently by sounds, which cause more irritation.

Abscesses about the urethra, perineum, and prostate, were frequently caused, as also fistulæ. Dessault and Chopart were of opinion that such abscesses should be left to nature, because they held that the urine could not get into them by keeping a catheter in the bladder and drawing off that fluid. Ducamp, on the contrary, states, that in many cases the urine will pass between the instrument and the canal, and readily find its way into the abscesses in question. Sir Charles Bell has known several cases of ulceration of the urethra extending to the neck of the bladder, induced by the continued presence of a catheter in the urethra*. Profuse suppuration has also characterized such cases, though the advocates of this plan are loud in their condemnation of cauterization, in consequence of its destroying the urethral mucous membrane. The presence of a sound in the bladder every day for a period of two or three months, must inevitably excite inflammation of the mucous membrane of that organ, more especially in aged persons, and ultimately induce catarrhus vesicæ. I agree with those who maintain that stricture is more likely to return after the use of sounds than of bougies. It appears evident that the treatment by sounds is much more painful and hazardous than that by bougies, with this additional inconvenience, that a palliative or temporary cure only is effected. The dilatation caused by sounds, though more suddenly established, is not more permanent than that produced by bougies. The fact is, when strictures are indurated, and the power of absorption greatly diminished, both these instruments can do little good until they have been employed for several months. It is only in the early stage of the disease, before the tissue is indurated, that absorption can be promoted, or at least is most available; but advice is seldom sought for until the disease has been long established. Under such circumstances, the most effectual

§ Dechamps's Tr. Histor. et dogm. de l'Operation de la Taille. See, also, Hunter on the Venereal.

mode for removing the obstruction is by destroying it with caustic or by a cutting instrument. This plan is now most generally employed on the continent, and is termed—

Treatment by Destruction.—The plan of treating strictures by bougies and sounds was generally found ineffectual by surgeons, who at length concluded that some other remedy should be adopted, which should be capable of destroying the obstruction without injuring the sound portion of the urethra. Two methods were proposed to accomplish the object in view; the one was to effect ulceration of the stricture by mechanical means; the other to destroy it by chemical agents.

The first method was attempted by passing bougies or sounds, and pressing these with considerable force upon the stricture from before backwards, and from without inwards. This plan was open to all the objections urged against bougies and sounds. If these caused acute pain, inflammation, abscesses, false passages, &c., they were more likely to do so when used with greater force, and when they were of greater volume and strength. Dessault, Chopart, and Hunter forcibly described the inconveniences of this plan, and related instances in which the urethra and rectum were perforated. It appears by the records of surgery that such injuries were often inflicted, and to obviate or prevent them, chemical agents were finally resorted to—and these were different caustic substances.

Treatment by Caustics.—Caustics were employed from a remote period, but they were chiefly used by Aldereto, Phillip, Amatus, Lusitanus, and Alphonso Ferri. The caustic preferred by these was composed of the following ingredients:—Verdigris orpiment, vitriol*, and roche alum, of each ζ ij; these were mixed with vinegar, exposed to the sun until dried, then moistened with vinegar, and mixed with ζ ij of lytharge and ζ iv of rose oil: they were next reduced to a proper consistence. This caustic was used as follows:—A wax bougie was passed to the stricture, an impression taken, the instrument withdrawn, the caustic applied to the indented part of it, and this was surrounded with wax. The instrument was then oiled and re-introduced.

But it was soon discovered that the wax bougie was too flexible, that the caustic came in contact with other parts of the urethra besides the strictured portion, and that violent urethritis was produced.

Ambrose Paré considered that retention of urine was sometimes caused by caruncles and carnosities, and that these ought to be cut and broken down with sounds, which he describes, and then destroyed with caustic. His instrument was a canula†, through

which he passed the following caustic powder:—Savin, ζ ij; ochre, antimony, and tutty, of each ζ ss. He terminated the treatment with bougies of wax or lead. He also used the caustic already described. Loyseau successfully treated Henry IV. of France, by this method*. Wiseman had recommended the application of nitrate of silver, by means of a canula, which was afterwards repropounded by Mr. Hunter. That great genius was not aware that the practice had been tried before him. There is a good excuse to be urged for him, and that is, that he thought for himself, and had scarcely any knowledge of the information afforded by the works of former writers. His nephew, Sir E. Home, however candidly admits that Wiseman had proposed the plan a century before his illustrious friend†. I have already described the caustic, or armed bougie, proposed by Mr. Hunter, and known to every surgeon. I have now to state, that its application, when judiciously made, causes such slight pain, that patients cannot distinguish it from that produced by a common wax or metallic bougie. In other instances, the whole urethra may be cauterized, and the pains the most acute.

The eschar, or slough, usually comes away in a day or two, in the form of a whitish pellicle. After the second or third application, there is more or less blenorrhagic discharge, in consequence of the inflammation produced by the caustic. The number of applications necessary for a cure will vary, according to the size and duration of the stricture: four, six, ten, or twenty, may be requisite in ordinary cases; but when the disease is of long standing, a hundred, or even double this number, may be necessary. Sir E. Home described such cases, in one of which the caustic was used 1,250 times (Treatise on Strictures, v. iii. p. 119). As the anterior part of the stricture only is cauterized, the patient perceives no amelioration until the posterior extremity of the obstacle is destroyed, and then the urine flows in a full stream.

The cures obtained by caustic are much more durable than by bougies or sounds. Many patients have no return of the disease for five, seven, or ten years; while many are radically cured. In other cases, the disease may return after a year or two. Sir Everard Home was of opinion that the return of the disease was to be ascribed to this, that the whole of the stricture was not destroyed by the caustic. Mr. S. Cooper has known many relapses after a cure had been apparently effected by bougies; Boyer corroborates the same statement‡, and Delpech asserts that the cure is only temporary§. Macilwain observes, that the gradual re-

† B. xix. c. 27.

removal of stricture does not always prevent its recurrence*. Such are the advantages of the treatment by the armed bougie, and they are great and incontestable. Nevertheless, this treatment is often productive of serious mischief. The inconveniences attending this plan are, the difficulty of destroying the whole stricture from before backwards, complete retention of urine, the liability to make a false passage, the danger of a formidable hæmorrhage, and, lastly, the probability of rendering the disease more obstinate and intractable.

I shall now examine these and other objections to the use of the caustic bougie. When the urethra is in a quiescent state, its parietes are in close contact; so that, on introducing an instrument, it separates them, and the caustic in the point of the bougie inevitably touches the surface of the canal in its passage on to the stricture. The urethra often, I might almost say invariably, contracts on any kind of instrument that is introduced into it; but, as its walls are in immediate contact, they must be inevitably touched by any thing that separates them. It is, therefore, manifest, that however rapidly a caustic bougie may be introduced, it touches the whole surface of the urethra, from its orifice to the stricture, and injures the sound as well as the diseased part of the canal. To this it has been replied, that the instrument may be passed so suddenly as to leave scarcely any time for the caustic to act in its passage; but still it acts, however slightly. If we apply nitrate of silver as quickly and as slightly as we can, on an external ulcer, the surface becomes instantly white, which proves the sudden action of the remedy. The same thing happens on passing an armed bougie. We observe, immediately after its use, that the patient complains of heat or pain along the urethra, and scalding on passing urine. On the next day, the symptoms will be more severe, and there may be a blennorrhagic discharge.

The advocates of caustic bougies suppose that this discharge is caused by the effect produced on the stricture, and not on the urethra anterior to it; but, granting them this, it is no answer to the objection urged. The discharge, according to their own showing, must be impregnated with the caustic when re-applied, and, therefore, must inflame the urethra in its passage onwards.

It is not unusual to observe, during the treatment with caustic bougies, the expulsion of whitish membraniform productions; and these will frequently present a tubal form. Such productions have been often observed by Ducamp†. They are caused by the action of caustic on the part of the urethra between the meatus and the ob-

stacle. When these eschars are detached, the canal presents an extended excoriation, and the urine, in passing, causes the most severe pains and smartings.

The part of the urethra anterior to the stricture may be most severely injured by the caustic, when it escapes from the bougie, and remains in the canal. Ducamp well observes, that the carelessness of the English surgeons is truly surprising, as they have not as yet found a means of fixing solidly a small piece of nitrate of silver in the end of a bougie. This is a matter of such little difficulty, yet the expedient that they employ is so imperfect*! In fact, the bougie is softened by the heat of the canal, the small portion of wax, which surrounds the nitrate of silver, has lost a great part of its consistence; moreover, the humidity of the canal may pass between the wax and the caustic, dissolve a part of the latter, and, therefore, the caustic affects the urethra. On one occasion Sir Everard Home attempted to remove the piece of caustic which had fallen into the urethra, by passing a bougie. The piece of caustic, which is detached, is about three or four lines in length, and two lines, or less, in diameter; it destroys half an inch, or more, of the urethra, gives rise to an infiltration of urine into the cavernous portion of the penis, causes frightful hæmorrhage, and, finally, a cicatrix, which impedes the flow of the urine.

One of the chief objections to this mode of treatment is, not to pass the instrument into the bladder until the treatment is on the point of being completed. We may diminish the size of the stricture without augmenting the opening; and if, in such cases, the application of the armed bougie produces inflammation, and complete retention of urine supervenes, then catheterism is much more difficult than in ordinary cases. Sir E. Home was frequently embarrassed by this event; and he was obliged to puncture the bladder in six such cases†.

It has been already stated, that we cannot, in general, pass a straight and inflexible instrument further than five inches, or five and a quarter, from the meatus, on account of the curve of the urethra; and, it therefore follows, that an armed bougie will not pass onwards in the canal, but form a false passage beneath the curve and towards the rectum. This will most probably happen in those cases in which the caustic is applied several hundred times. Indeed, Sir E. Home confirms this conclusion when he says, "It is an operation in the dark, and the most skilful operator may sometimes be mistaken." Besides, the repeated introduction of the armed bougie, must inevitably disorganise the mucous membrane of the

* On Strictures of the Urethra.

* *Op. cit.*, 169.

† See vol. ii, p. 323, and vol. iii, p. 2.

urethra, for the reasons already assigned. The inferior part of the urethra will be most affected by the caustic, which becomes dissolved during the operation; and hence there will be a false passage under the natural one. This will happen in those cases in which a great number of applications of the caustic are indispensable.

The next objection to this mode of treatment is, the induction of hæmorrhage from the urethra, to the amount of several pints in some instances. Profound syncope, and great prostration of strength, have succeeded; but it rarely happened that life was destroyed. The blood may find its way into the bladder, form a clot, and cause complete retention of urine. Sir E. Home states, that such clots are generally dissolved by the urine in the course of twenty-four hours. He advises, that the hæmorrhage should be left to itself; and he cites a case, in which the bladder was entirely filled with blood*. Sir A. Cooper, with more judgment, applies a compress on the urethra, in its course beneath the pubes; and, in one case in which the hæmorrhage returned, he divided the artery of the bulb†.

Another inconvenience arising from the use of the armed bougie is, that the stricture may be rendered more obstinate and intractable. This may occur after several applications of the instrument; as, in such cases, the mucous membrane, anterior to the obstruction, will be destroyed, and a firm contraction or stricture induced. This fact is well known to those who have had much experience in the use of the caustic bougie; and, also, that such indurations will seldom yield either to this method or that by dilatation. It is also a well known fact, that the general health suffers, and that this plan may be followed by all the worst consequences which are detailed in this essay.

The objections to the armed bougie of Hunter, are still greater to the caustic potass instrument of Whately. This generally produced the worst consequences, on account of the greater solubility of the pure potass, so that it has been long since abandoned in this country‡. It had little effect on the stricture. Sir Charles Bell relates the case of a man to whose stricture it was applied, and who died of inflammation of the lung. On examination, he states that "no spot, no abrasion, no slough, were to be seen, the bridle of the stricture remained sharp and fine." (Treatise on the Urethra, p. 357). Such was the mode of applying caustic until 1822, when M. Ducamp pro-

posed his unobjectionable method, which I have already noticed.

This ingenious surgeon invented proper instruments for applying caustic, and these, as well as his graphic description of the pathology and treatment of stricture, were most favourably received by the Institute of France, and declared to be the best ever offered. M. Ducamp, after the most minute examination of the anatomy, pathology, and modes of treating strictures of the urethra, proposed this problem: "*To destroy the morbid disposition of the parts which form the stricture; and to place them again on a level with the rest of the canal.*" He adds, "If we can destroy the parts that constitute the stricture, we obtain a thin, elastic cicatrix, and re-establish the passage, as large as the canal in a state of health, we shall have, I think, obtained our object*." And, according to this author's view, the caustic ought to be applied to the stricture only from within outwards over its whole extent, and without touching any other part of the urethra; for example, when the opening of the stricture is inferiorly, we should destroy all that part which is between the opening and the superior wall of the canal, without touching the inferior wall, and the reverse. When the parietes of the stricture are two, three, or more lines in length, they should be touched from before backwards along their whole extent; but, before we use the caustic, we should ascertain the site of the aperture of the obstacle, and the extent of this last. M. Ducamp acquired this knowledge by the following ingenious mode of investigation:—

He took, with an instrument of his own invention, which he names *sonde exploratrice*, an impression of the stricture; this impression is formed exactly by the stricture, and enabled him to know with mathematical precision the parts which are to be destroyed, and during the progress of the cure, all the changes that the obstacle has undergone.

It appears, however, from the statement of Dr. Arnott, already given, that our Gallic contemporary had borrowed his ideas from Dr. Arnott; though I think it must be acknowledged that he improved upon them. His description of stricture is far superior to any that had preceded it.

The next instrument he invented was a conductor; this was a gum elastic tube pierced at the extremities, with a scale on its surface, to indicate the extent which the instrument might penetrate. He passed this instrument to the obstacle, and when the stricture is superiorly, inferiorly, or laterally, he used one furnished with an eminence at its extremity, which is turned downwards when the stricture is above, and the reverse. This instrument enabled the operator to pass

* Work, vol. iii, p. 257.

† Lectures on Stricture, 1824.

‡ Sir B. Brodie prefers it, however, to the nitrate of silver.—Lectures on Diseases of the Urinary Organs. 2nd Ed. 1835.

* *Traité des Retentions d'Urine*. Par Theodore Ducamp, M.D., &c. Paris, 1825.

a bougie through it, and to touch any kind of obstacle in the urethra with the greatest facility. M. Ducamp invented another instrument with a small head, to be passed through the conductor and along the stricture, so that the extent between this head and the extremity of the conductor, indicated the length of the stricture. But he used a more simple contrivance, a bougie with soft wax on its extremity, on which the stricture made an impression, which indicated the form of the obstacle. Having acquired an accurate knowledge of the form and extent of the stricture, he applied his *porte caustique*. This instrument is composed of platina at the extremity, in the side of which the nitrate of silver is fused with a blow-pipe. This passes through the conductor, and may be applied to the stricture wherever situated, if within five inches or more of the urethral orifice, by turning it round between the fingers. By this proceeding, the part of the canal anterior to the stricture is not touched by the caustic. The stricture is cauterized from before backwards in all its extent, and of course from within outwards.

Two applications were sometimes sufficient to destroy the obstruction; sometimes a third was necessary, but very rarely a fourth, and during each one-tenth of a grain of nitrate of silver was employed. Having destroyed with precision the stricture, M. Ducamp proceeded to fulfil the second indication, to restore the canal to its natural state, about four lines in diameter. He employed two instruments for this purpose—a *dilator* and a *bellied bougie*.

The dilator consisted of a pouch of 15 or 18 lines in extent, which, when inflated, expanded about 4 lines. Its pressure is temporary, and therefore the bellied bougie is employed at the same time. This is a common bougie, on the part of which that corresponds to the strictured portion of the canal is a protuberance or belly, from two lines and a half in diameter, and 12 or 15 lines in length. This projection is placed against the side of the stricture, which it distends, while the rest of the instrument is adapted to the size of the urethra.

There is some difficulty in passing the instrument through the orifice of the urethra, which is about $2\frac{1}{2}$ lines in diameter; but as it is dilatable, it readily expands and allows the bougie to advance. M. Ducamp states that he has dilated a stricture in three days with bellied bougies, varying from two lines to four in diameter, for which the ordinary mode of dilatation had been unsuccessfully practised for two months. Thus observe MM. Deschamps and Percy, the reporters to the Institute—"M. Ducamp arrived at the end proposed; he has found the means of destroying, with the greatest precision, the obstruction of the urethra, without injuring the sound parts of the canal, and obtained a cicatrix of four lines in diameter. It ap-

pears to us that he has discovered a mode of treatment more short, more simple, more certain, more reasonable, and we think that M. Ducamp has acquired real claims to the confidence of the sick, the gratitude of the profession, and that his work deserves the eulogies of the Academy."

The limits by which I am circumscribed in this essay prevent me from quoting this author as I could wish, and I must content myself with the extracts now made. I may observe that his practice is now universally adopted on the continent of Europe, and has recently been improved upon by Mr. Phillips, in his work on Diseases of the Urethra. I have already noticed the improvements suggested by M. Lallemand, namely, insertion of a curved *porte-caustique* when the stricture is more than five inches from the urethra, and this Mr. Phillips has also introduced in place of his own. It is right to state that the caustic is applied by Ducamp and Delpach for about a minute, and sometimes less, and the eschar is expelled in three, four, or six days. When the stricture is reduced he explores the urethra towards the bladder, and when he discovers a second or third obstruction he cauterizes the latter at the same time as the former, and in this way he cures both in a very short space of time, and with little additional pain to the patient.

Some surgeons object to dilatation, and contend that it excites inflammation, which reproduces stricture. We should, however, be guided by the effects caused by bougies, and be cautious in using them, if irritation or acute pain is produced.

During this or any other treatment of stricture, the general health should be attended to, the diet should be more nutritious, all spirits, wines, and fermented liquors avoided; demulcent drinks, general or local baths, and sometimes leeching employed. It is right to mention that stricture may return even after cauterization, so that it would be prudent for the patient to pass a bougie once a month, to ascertain the condition of his urethra. In general, false passages soon disappear when the urethra is restored to its ordinary calibre.

I have already stated, that the potassa fusa is seldom used by the majority of British surgeons at present; but it is proper to mention, that it is very strongly recommended by Mr. Macilwain in all cases in which there is severe pain in the stricture, and the effusion of blood after a bougie is withdrawn. He has used the remedy in all cases of this kind, and has never had reason to regret the practice. Mr. S. Cooper, on the other hand, condemns this caustic, in strong terms, in his Dictionary of Surgery. The former states, that the nitrate of silver is now seldom used, and that it is superior to the potass in those cases in which there is no pain in the stricture before or after the use of a bougie. He never employs it

more than three or four times, unless benefit is derived from its use. The interval between each application must depend upon the degree of irritation excited in the urethra. This rule applies equally to the use of unarmed bougies or sounds. Some persons will bear the caustic once or twice a week; others, not oftener than once a fortnight.

Mr. Stafford is of opinion, that a bougie should not be passed oftener than twice a week; and, if there be any inflammation, a wax or an elastic instrument ought to be preferred. But, afterwards, he prefers the metallic or silver catheter—"having observed, that the cure of stricture, by these instruments, is more permanent; they resist spasm, and you have more command over them."

When stricture has existed for a long time, and nearly closes the urethra, the patient is often unable to pass urine, except in drops; he strains violently, and suffers extreme agony. His general health becomes injured, and he is finally affected with complete retention of urine. Under such circumstances the bladder will become distended, and much bent, unless a catheter can be passed, or a puncture made into it. In such cases the surgeon must adopt one of these plans; he must endeavour to pass a catheter into the bladder, and, if he cannot succeed, put the patient in a warm bath, employ venesection, leeches, or fomentations. If these fail, we must puncture the bladder, or cut down on the stricture, incise it, and then introduce a catheter into the bladder. Of these methods, catheterism and incision of the stricture are now most generally employed. When the first fails, the second must be practised, or the bladder must be punctured.

Reviews.

The Cyclopædia of Anatomy and Physiology.
Edited by Robert B. Todd, M.B., Lecturer
on Anatomy and Physiology at the Westminster School of Medicine. Part II. August, 1835. London: Sherwood, Gilbert, and Piper. Illustrated with numerous Engravings.

THE favourable opinion we pronounced on the first part of this work is confirmed by the execution of the part now before us. The just tribute of praise we bestowed on the respectable publishers of it is now amply increased by the typographical execution of the present fasciculus.

The present number contains the following articles: Animal Kingdom concluded, by Dr.

Grant; Animal, by Dr. Willis; Ankle, Region of, by Dr. Brennan; Ankle, Joint of the, by Same; Ankle Joint, abnormal condition of the, by Robert Adams, Esq.; Annelida, by Dr. Milne Edwards; Anus, by Robert Harrison, Esq.; Aorta, by Dr. Hart; and Archnida, by Dr. Audoin.

We have perused all these articles with great attention, and can consistently declare that they are executed in a manner not excelled and seldom equalled by writers in the most popular cyclopædias of modern times. They are worthy of British and foreign authors, and are in exact accordance with the present state of science in all civilized countries.

The announcement and scientific execution of the work is highly creditable to its editor and publishers, and honourable to this country. Every article is treated in the best manner; many illustrated as close to nature as it is possible for art to accomplish, and a mass of information presented, which can only be found in an immense series of foreign and British works. This cyclopædia is a library in itself, and ought to be in the possession of every medical practitioner. We take no small degree of credit to ourselves for the manner in which it is executed. We felt it our duty to criticise many blemishes and defects in a work somewhat similar in point of issue, from the same source. We complained of many articles as totally unworthy of that work, while we praised all that deserved commendation. Other reviewers were more accommodating: their unbounded adulation was disgusting, and they praised articles that ought to have undergone a fiery or fundamental ordeal; in fact these were unparalleled. Now, this kind of wholesale praise does a work more harm than good; and we know from a vast number of sources that it was ridiculed and despised. Our strictures, however, though unpalatable amidst such false praise, effected improvement; the faults we exposed were corrected, good was one, science was benefited, and all grounds of complaint entirely excluded from the succeeding publication now before us.

It is true that great allowance ought to have been made for a production of the kind to which we have alluded, but the selection of

the contributors was by no means fortunate. Dr. Todd has been more judicious, and the result is, that his *Cyclopædia of Anatomy and Surgery* is so admirably executed, as almost to set criticism at defiance. If the future parts equal the present, the work will be a monument of science and industry, an ornament to the literature and science of the age and country in which we live.

It is scarcely necessary to observe, that productions of this kind do not admit of analysis. To attempt it with justice to our readers or the authors, we should republish the whole of the work. This would be obviously impracticable. We must therefore content ourselves, with an honest and fearless expression of our opinion of it, with which our readers must be satisfied, until they can judge for themselves by possessing the original as early as possible, which we strongly advise them to do.

In conclusion, we have to state, that in our judgment every one of the writers whose names appear in a preceding sentence has performed his part with the greatest credit to his scientific reputation.

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

(Continued from p. 28.)

THE abdominal cavity never contains any fluid, except such as may have been effused before death; on the contrary, the viscera have a tendency to become progressively drier, and they present very little humidity a few months after inhumation. The state of the organs contained within the abdomen is such, as to surprise those who are little accustomed to researches of this nature: while the abdominal parietes are entire, the subjacent viscera preserve their integrity, their shape, and even their relative position; on opening the abdomen, all the contained parts are easily distinguished, till the parietes are nearly in contact with the spine, and the viscera much diminished in volume. Later than this, the confusion is greater: the liver, spleen, and kidneys are recognised, rather by their situation than their form; and, in place of the alimentary canal, nothing is found but a mass of shrivelled membranes, which are evidently the remains of the stomach and intestines, because, on separating them, the cavity of the former, and part of that of the latter, are restored. These dry layers are

of a greenish brown colour, thin, and perforated at certain points; the cavity of the intestinal canal cannot be restored throughout the whole, nor even the greater portion of its length, and we can no longer distinguish its different parts and constituent tunics—still less can we detect any morbid alterations that may have resulted from the disease which proved fatal. Still later, we discover nothing but a dry foliated mass, the interior of which is often full of worms, and which may be separated into coraliform filaments: at one part only of this mass some vestiges of the cylindrical shape of the intestinal tube may be recognised. Finally, as we have already observed when speaking of the parietes of the abdomen, there remains nothing in its cavity but a small quantity of black matter, resembling the grease of a wheel.

The Limbs.—During the first weeks the limbs present nothing remarkable. The skin is deeply coloured, except on those parts of the arms which are in contact with the thorax and abdomen: here it preserves its natural colour, but is covered with an adhesive reddish mucosity, which appears to glue the arms to the trunk; and, when these parts are separated, the epidermis is detached. At a more advanced period, as the integuments and muscles putrefy, the bones become partially denuded, but retain their articulations, since the ligaments are not yet destroyed. At this time those portions which retain their flesh, are found in two different states:—1. The soft parts are impregnated with earth, white mould, and the debris of the cloth in which the body has been enveloped; they have the appearance of a solid substance, foliated, and as if cancellated externally, under which hollow spaces are observed. This substance is evidently formed of fibrous and aponeurotic parts, without the least trace of adipocere; when it is cut into, a considerable number of worms and flies escape. Sometimes, also, this layer is of a stringy texture, and cellular appearance, unctuous to the touch, one or two inches thick in many parts, and covered externally with a crust of adipocere; while, internally, it resembles rotten wood, except that the filaments composing it are moister, and present here and there the characters of the animal fibre. 2. The soft parts are reduced to a thin, dry, grayish stratum, covered, in some places, with white mould, and divisible into two laminæ, of which the external appears to consist of the skin, and the internal of the aponeurotic parts, or at least of a layer equally thin: the internal lamina is spongy, stringy, dry, and of the colour of tinder; neither vessels nor muscles are any longer distinguishable in its substance.

At a more advanced period, the bones are detached from their connections by the smallest effort, the ligaments offering very

little resistance, and only a few remaining filaments of the soft parts keeping them together: in a little while the bones no longer retain their connexion, though they preserve their relative position; and, finally, when all the bonds of union are destroyed, they become completely separated, and are found scattered in the coffin, the winding sheet, or the earth.

Coffin.—*Cæteris paribus*, the thinner the wood of which the coffin is made, the sooner it is decomposed. In general no change is observed, even in thin coffins, till the end of several weeks. The internal surface of the lower board at first assumes a blackish gray colour, spotted with black; it becomes mouldy, especially where the head and back rest upon it, and there is a considerable quantity of a brownish and very fetid pulp, covered in many places with worms, larvæ, and eggs: soon after, the external surface of the lower board becomes coloured, and covered in the same manner. The sides of the coffin are inclined outwards, and somewhat bent; they are brown, or here and there gray, and lined, as it were, with larvæ. The bottom of the coffin soon becomes perforated in several places, and seems as if worm-eaten; the wood around the perforated parts is black, and has a greasy appearance: here, also, a shining, fatty matter, not so dark in colour, is sometimes to be seen. Lastly, we find, in the bottom of the coffin, thousands of larvæ, and of worms, some of which are ten lines in length. At this time the lid is sunk, and broken in several places, so that the earth has reached the bottom of the coffin. Later than this, it is difficult to raise the coffin without breaking the sides and lid; the fragments of these parts are variously coloured, especially on their inner side, with yellow, white, black, and wine colour, and, in some places, resemble the interior of an old cask; the wood is so rotten, that it may be crumbled between the fingers. Finally, the coffin becomes so fragile, that it can only be removed by small fragments.

According to our experiments, the coffins were in this state at the expiration of thirteen or fourteen months, when they were made of thin deal; but when constructed of the same wood an inch in thickness, they remained entire, and were scarcely coloured yellow, externally, at the end of two years.

(*To be continued.*)

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE fifth meeting of the British Association is now being held in Dublin, and commenced Monday, the 10th instant.

The increasing success of the Association is a gratifying proof that the objects ori-

ginally contemplated—to promote personal intercourse between men of science—to make them quickly acquainted with each other's views and discoveries—to elicit oral discussion upon contested points—to procure, by special request, reports on the existing state of science in its several departments, with suggestions for future improvements, &c.—have been, in a large degree, attained. The members of the association, at the first meeting held in York, amounted to three hundred and fifty; when the society assembled at Oxford in 1832, the number was about seven hundred; the meeting at Cambridge was attended by more than nine hundred; the numbers last year at Edinburgh amounted to twelve hundred and ninety-eight; and it is confidently expected that the meeting in Dublin will not, in any respect, be inferior to those which have preceded it, though many who would have taken an active part in its proceedings, will be detained in London by the unusually protracted session of parliament; a circumstance which could not have been foreseen when the day of meeting was fixed.

The Rules of Admission to the Society were the following:—Fellows and Members of chartered literary and scientific societies, publishing transactions, were entitled to become members of the association, on subscribing an obligation to conform to its rules, and paying their subscription or composition. Office-bearers, members of council, or managing committees of philosophical institutions, and other members, recommended by such councils, were entitled in like manner to become members of the association if duly recommended and approved of by the General Council. The annual subscription is 1*l.*, paid in advance upon admission. The composition, or life-subscription, is 5*l.* Members, and candidates for admission, applied at the Examination Hall of Trinity College.

The officers of the Association for 1835 are—

President—Rev. Bartholomew Lloyd, D.D. Provost of Trinity College, Dublin.

Vice Presidents—Lord Oxmantown, and Rev. William Whewell.

Secretaries—William Rowan Hamilton, Astronomer Royal of Ireland, and the Rev. Humphrey Lloyd, Professor of Natural Philosophy.

Treasurer—Thomas Henry Orpen, M.D.

The following was the order of business:—

The meetings of the General Committee were held in the rooms of the Royal Irish Academy, 114, Grafton Street, nearly opposite the College. The first meeting was held on Saturday, the 8th of August, to make the necessary arrangements for the business of the week.

The Examination Hall of Trinity College was the place of general rendezvous, for supplying information to strangers, and is-

uing tickets. Ordinaries were provided for the accommodation of the members, in convenient situations. Plans of these ordinaries were exhibited every morning in the Examination Hall, so as to enable members to select their places. Lists of lodgings were likewise exhibited in the same place.

The Association is divided into six sections, which meet every day during the week, between the hours of 11 A.M. and 3 P.M., at the following places:—

SECTION A.—*Mathematics and General Physics*, at the Philosophy School, Trinity College, situated over the Dining-hall.

SEC. B.—*Chemistry and Mineralogy*, at the Chemical School, Trinity College, situated at the east end of the College Park.

SEC. C.—*Geology and Geography*, at the theatre of the Royal Dublin Society. The house of the Royal Dublin Society is in Kildare Street, and was formerly the residence of the Duke of Leinster: it contains an excellent library and museum. Members were allowed to pass into Kildare Street, from the College, through the Fellows' garden, a door from which opens nearly at the top of the street, and thus the advantage afforded by the use of these excellent rooms was not neutralized by their want of concentration.

SEC. D.—*Natural History*, at the Board Room, Royal Dublin Society. The museum of this institution is rich in objects of Natural History, affording favourable opportunities for reference.

SEC. E.—*Anatomy and Medicine*, Board Room, Royal Irish Academy. The house of the Royal Irish Academy is at the north extremity of Grafton Street, nearly opposite the College.

SEC. F.—*Statistics*, Divinity School, Trinity College.

It has been very properly suggested in the circular of invitation, that members, who may have papers or other communications to lay before the Association, should state their general nature and probable extent, in a letter addressed to the secretaries of the sections, at the house of the Royal Irish Academy, as early as possible. Unless attention be paid to this recommendation, great inconvenience would arise, and valuable papers might be neglected in the press of business. Investigations of considerable length were recommended to be presented in abstract. The subjects that are to engage the attention of the sections, are posted each day on the doors of their respective places of meeting, and also in the College Examination Hall.

The general meetings of the Association are held in the rooms of the Rotunda, on three evenings (Monday, Wednesday, and Friday), during the week, at 8 P.M., and there will be a concluding meeting on Saturday before dinner. Members and their friends are expected to assemble in these rooms on the other evenings of the week, for the purposes of friendly intercourse.

The Rotunda stands at the northern extremity of Sackville Street. The apartment in which the Association assembled, is a circular room of about eighty feet in diameter; there are few places in which a speaker can be heard so distinctly. The road from the College to the Rotunda is through Westmoreland Street, Carlisle Bridge, and Sackville Street, in nearly a straight line, and passes by some of the finest buildings in Dublin; the Bank, the Custom House, the Post Office, &c.

On the first evening one of the secretaries read a report on the effect produced on the progress of science by the labours of the Association during the past year.

On one of the other evenings Dr. Lardner delivered a lecture on locomotive engines and rail-roads. A practical illustration of such subjects will be afforded by a trip to Kingstown by the new rail-road; it being the intention of the committee that the ordinary shall be provided at Kingstown on one day during the week, so as to give the members an opportunity of seeing an interesting part of the environs of Dublin, without sacrifice of time.

Ladies were admitted by tickets to the general meetings of the Association, but not to the sectional. Ladies' tickets were issued as extensively as possible, especially to ladies from England or Scotland, who came to Dublin during the meeting.

The museums of the Royal College of Surgeons, and of the Dublin Society, the Zoological and Botanical Gardens, and the other public institutions were open during the week to members of the Association. The neighbourhood of Dublin and the natural beauties of an adjoining county, will offer many inducements to strangers to prolong their stay, when their scientific labours are concluded.

Many English geologists of eminence are understood to be engaged in examining doubtful points in the geology of Ireland, and it is hoped that geological parties will be formed after the close of the meeting, to explore some of the most interesting portions of the same country.

MR. RENSHAW'S REPLY TO MR RUSH.

To the Editor of the London Medical and Surgical Journal.

SIR—In your Journal of the 8th inst. I observe a statement, purporting to come from a Mr. Rush, which is said to have been extensively circulated among the members of the medical profession, and in which my conduct is reflected on in severe terms. As you have not hesitated in giving insertion to an *ex parte* statement, I claim the privilege of an injured man, and demand an opportunity of replying in the pages of the same Journal in which this injurious article appeared.

It can scarcely be necessary to enter into an examination of the whole statement

which is inserted in your last number; the principal points which the author calls "facts," I shall select and comment on, and thus your readers will be enabled to judge whether of the twain has most right to complain of improper conduct. (Here follows a quotation from Mr. Rush's statement in our last.

The truth of this I deny altogether, not solely on my own authority, but I shall support my denial by a letter (which is appended) from Mr. Dobson, surgeon, of Princes' Street, Westminster, and on which no remarks can be needed—it speaks for itself. I did not make any application to Mr. Rush, the *sub-editor* of the journal, for his lecture, nor did he ask permission for its insertion, either of the editor or myself, and consequently the condition to which he alludes cannot have had existence, save in his own imagination. I was not even aware that it would be inserted, until late on the Wednesday evening, when a proof sheet was sent me in which it appeared. I immediately wrote to him requesting he would withdraw the lecture altogether, or else remove his name. I gave him ample opportunity to do this; but finding, at the eleventh hour, that the lecture remained unchanged, his name was certainly struck out, as I deem I had a right to have done, being the managing proprietor, and also having the largest share and the deepest interest in the success of the work, as I had advanced all the pecuniary assistance to carry it on.

I will now, Sir, leave the members of the profession to draw their own conclusions, and to form their judgment as to the conduct of a man who could deliberately and wilfully make a statement evidently intended to do me serious injury, and that so totally at variance with the truth. For myself I pity and forgive him. I am, &c.

HENRY RENSHAW.

136, Strand, August 12th, 1835.

DEAR SIR—It is with great pain that I feel myself called upon to interfere in the dispute between you and Mr. Rush; and the reluctance I feel in doing so is not lessened by the circumstances that connect Mr. Rush and me together. Anxious, however, to act impartially between you both, I cannot hesitate to repeat in writing what I expressed to you in person respecting the publication of Mr. Rush's lecture in your journal. Mr. Rush called upon me in the early part of the week in which his lecture appeared, and stated to me that it was his intention to insert it in that week's number, and was anxious that you should not be aware of the circumstance, alleging as the reason, that if you were, you would prohibit its insertion. He requested that if I should see you I would not notice the matter. Yours truly,

W. DOBSON.

Westminster, Aug. 12th, 1835.
To Mr. Renshaw.

[We publish this communication, but ap-
prize all concerned, that they must look
elsewhere for the medium of publishing fur-

ther correspondence. We cannot allow them to occupy our pages with their personal squabbles.—Ed.]

The London Medical
AND

Surgical Journal.

Saturday, August 15th, 1835.

DISPENSARIES—THE GRATUITOUS
HUMBUGH.

WE have lately received many communications on the subject of dispensaries, and as it is one of considerable importance both to the profession and to society, we shall briefly state our opinions thereon, and call the attention of our readers to a few prominent facts, in justification of what some may think a harsh conclusion.

On weighing the good against the evil, as impartially as we are able, we have no hesitation in expressing our belief that dispensaries, *as they are at present constituted*, are a decided nuisance. They are beneficial in as much as they afford medical aid to a certain number of necessitous persons who might otherwise be unable to obtain it; they are prejudicial for the following reasons, which we adduce, not in the order of their importance, but simply as they occur to us.

I. Dispensaries are adverse to the interests, and derogatory to the character of the medical profession. They are adverse to the interests of the profession, because young practitioners, in the very delusive persuasion that their connexion with a dispensary will ultimately introduce them to the favourable notice of the public, are wont to offer their services *gratuitously*; as a necessary consequence of which, they are regarded as a kind of professional *hacks*: since they put no price upon their own time and labour, it is not wonderful that others should make light of them, and be disposed to draw pretty freely upon both; accordingly, there is no vrier slave under heaven than your dispensary doctor; he is tormented by unreasonable patients, and badgered by their more unreasonable patrons. Again,

dispensaries are derogatory to the character of their medical officers, for the same reasons that they are prejudicial to their interests; a man who allows himself to be made a *hack* is never respected—the best feeling that is extended towards him is a kind of ludicrous compassion; but the general disposition is to get as much work out of him as possible; hence, the dispensary doctor is continually subjected to every species of impertinence from those charitable busy-bodies, who take a tender interest in the welfare of the poor, where it can be promoted without the smallest inconvenience or expense to themselves; and nothing is more common than for a semi-medical parson, or lady-bountiful, to send a message to the doctor in the middle of the night, requesting his immediate attendance on a patient who, according to the rules of the institution, may have no claim to his services, and may also happen to have little or nothing the matter with him; if, however, the doctor do not turn out forthwith, he is a manifest brute, and has not a drop of the milk of human kindness in him.

Such are a few of the pleasant results of the *gratuitous system*. Formerly the public was in some degree deluded by this system; people thought that, although the doctor had doubtless some private motives, still it was a most charitable and amiable thing in him to undertake the gratuitous care of the sick poor: but all this has gone by; and the doctor is now merely regarded as what he is—an egregious ass—for working for nothing.

“Oh pardon us that we descend so low,
To show the line, and the predicament,
Wherein ye range under this subtle *system*.”

The physicians and surgeons are the only officers connected with dispensaries who are not paid; the apothecary, the secretary, the collector, are all paid—in short the only persons unremunerated are those whose services are most indispensable to the charity, and most laborious to themselves; for this, how-

ever, the medical men alone are to blame—they ask nothing, and they get what they ask, which is all fair, and in strict consonance with the principles which regulate the business of the world.

The infatuation of the profession on this point is really deplorable; not only does the dispensary doctor give an immensity of time and labour for absolutely nothing, either present or in reversion, but he is continually losing the means of private advancement through the distractions of his falsely called charitable duties. We have known dispensary physicians lose the most important opportunities in private practice, by going to visit dispensary patients, who, when visited, could not tell what was the matter with them!

2. Dispensaries fulfil very imperfectly the object of their institution, which is to afford efficient medical assistance to the poor. They are inadequate to this end for two reasons; one is, that the number of patients is usually altogether disproportionate to that of the medical officers; consequently those patients who attend at the dispensary have their cases very superficially investigated, while many who ought to be visited at home are compelled to attend, as long as they are able to crawl, from the simple inability of the medical officers to sustain the personal fatigue of visiting so great a number. We speak from experience; we have ourselves repeatedly been obliged to prescribe for a crowd of patients at a dispensary, in so short a time that it was utterly impossible for us to take proper cognizance of their cases, and we have left the institution with the unpleasant feeling, that what little skill we possessed, had not been fairly exercised in behalf of these individuals; again, we have repeatedly been obliged to desire patients to return to the dispensary, who ought to have had attendance at home which it was not in our power to give them. Another reason why dispensaries are inadequate to the end proposed is, that even supposing

the cases which require attendance at home to be duly provided for, such patients must very frequently be treated in opposition to the noise, filth, stupidity, and brutality, which too often surround the sick bed of the poor, and render the resources of medicine little better than nugatory: the truth is, the greater part of the cases visited by the dispensary physician ought to be in an *hospital*, where they might enjoy the advantages of quiet, cleanliness, good ventilation, proper care, and proper regimen.

3. Dispensaries, considered as *charitable* institutions, too frequently lend their aid to very improper objects. Many persons who would scarcely have the impudence to present *themselves* as objects of charity, become subscribers to dispensaries, for the laudable purpose of getting their poor relations off their hands when they are ill; and many wealthy persons subscribe to dispensaries chiefly on account of their servants, for whom, if generously disposed, they might very well afford to pay—to say nothing of the fact that the servants can generally very well afford to pay for themselves.

4. By the admission of such patients as those above mentioned, dispensaries stand very much in the light of the younger general practitioner whose principal business for some years lies among persons in the lower classes of society, who, nevertheless, may reasonably be expected to pay something according to their means.

Such are the chief circumstances which render dispensaries *injurious*; but it is not to be forgotten that the new poor law act renders them in a great measure *superfluous*, because it empowers the commissioners to procure advice and medicine for the poor in their respective parishes, and to *remunerate medical practitioners for the same*.

Still, however, there is a class to whom dispensaries might be very useful if they were placed on a rational basis,

and in a just relation to *hospitals*. On the one hand, dispensaries cannot, generally speaking, extend any very effectual assistance to cases which require to be visited at home; and on the other hand, hospitals have quite enough to do if they attend properly to their in-door patients; we should say, therefore, let dispensaries confine themselves to such cases as are able to attend at the institution, and let hospitals give up their out-door patients who, under the present system, are generally very much neglected: let dispensaries also engage medical gentlemen of well known skill and experience, and remunerate them properly for their trouble, instead of allowing unpractised lads to acquire, at the expense of the poor, experience to be afterwards exercised for the benefit of the rich. Dispensaries, if thus constituted, might be of considerable utility, instead of being, as they now are, a very serious evil to the medical profession, and a very doubtful benefit to any body.

There are several minor abuses in dispensaries, which it scarcely falls within our province to notice, but which well deserve the attention of the public; such as the practice of tradesmen becoming subscribers, merely for the chance of supplying the institution with their particular commodity, and charging whatever they please for it—an indulgence too frequently conceded to such *disinterested* promoters of public charity: this evil would be best obviated by enacting that no subscriber shall supply the institution with anything.

We cannot conclude without entreating our brethren to reflect, that the evils of the dispensary system which bear upon the profession, are entirely attributable to our own folly in working for nothing—a thing not done even by the clergy, who, of all men, ought to be the most disinterested, and the least worldly; and we earnestly entreat the profession, in this, as in all other instances, to offer a strenuous resistance to the *gratuitous humbug*, which we, for our own part,

shall lose no opportunity of exposing and counteracting.

—o—.

MILITARY AND NAVAL SURGEONS.

WE have long considered that there is no portion of our profession so badly treated as those of our brethren who have been so unfortunate as to belong to our army and navy. It is melancholy to reflect, that well educated, scientific, and most experienced medical practitioners, should be subjected to the harshest exactions, to years of servitude, and to the most inadequate remuneration for their services. If we trace them through every clime, however pestiferous, through every engagement, however glorious to our country, we find them by far the worst treated of our naval and military officers. Some of them have been a score of years as assistant surgeons, with less pay than would satisfy an unwashed mechanic. Merit was not rewarded unless interest was behind the scene. We have had the good fortune and happiness to be associated with a vast number of naval and military medical officers, and we can honestly declare, that better informed or more judicious physicians and surgeons cannot be found than amongst them. But their rewards are most pitiable. Their compensation, not remuneration, for many years' services, say twenty or five and twenty, is disgraceful to the past and present government. It would not be very unreasonable to hope and expect, that a monarch, who like our brethren, passed through the gradations of one of the services which we have mentioned, might improve, and there is vast room for improvement, the condition of our naval surgeons. It would not be unreasonable, in our humble opinion, to expect, that naval and military surgeons might be placed on the same footing, however miserable that footing may be. Neither would it be unreasonable to contend that their emuneration, or call it pay if you

please, should be double what it is; for who can deny that the services of a surgeon are infinitely more valuable than those of any officer, unless one in command, and often more so than his.

We can perceive no valid reason why the services of twenty years should receive no greater reward than a parish clerk's; nor can we understand why a military or naval surgeon or assistant, on his munificent half pay, which is scarcely enough to procure him and his family the necessaries of life, should be deprived of it, or half of it, by what is called compounding, when after many years' exertion in private life, he has succeeded in practice, unless he go again on active service, which was so valuable to him. Only think of the notion of a surgeon with a large family, who spent twenty years in the army or navy, retiring on 150*l.* a year; and after having succeeded in private practice, being called on to go on active service, or forfeit his beggarly half pay. This is Scotch economy with a vengeance: a few hundreds will be saved to the nation, and the Chancellor of the Exchequer for the time being, cannot fail to open his budget with pleasure at the result. The reader will exclaim, it is impossible that this state of things can exist, when we have medical directors-general of the army and navy. We tell them, however, our statement is too true. Whether these public officers are content with their own extravagant pay we know not; but we well know that their brethren have no reason to thank them for any attempt to better their past or present condition, though in many instances their superiors in learning and science.

We should like to know from the directors-general of army and naval medicine, on what grounds there are not medical schools at Haslar, Greenwich, Chelsea, Plymouth, and other national hospitals of the army and navy? It assuredly cannot be for want of talent, as our Guthries, Hennens,

Ballingalls, Coopers, Hutchinsons, Veitchs, Hametts, &c., are among our best medical writers, and some of them our most popular teachers of medicine. We leave the scientific directors-general to explain these questions, and at the same time must be permitted to inform them, that they have neither done their duty to their country nor profession.

Dr. Alexander's Reply to the Medical Gazette.—Just as we had penned the foregoing remarks, we received the communication from Dr. Alexander, a staff surgeon in the British service. It clearly shews that he has been very unfairly treated by our worthy contemporary. We shall only offer one remark on the subject, that of all medical practitioners, the military and naval are the least likely to give false certificates of health to their brother officers, and no one who knows any thing of either service, would credit it for a moment. There are, however, reasons why our contemporary should have fallen foul of Dr. Alexander, but these shall remain editorial secrets at present. As friends to justice, our pages and pens will always be at the service of our military and naval brethren.

—o—

THE MEDICAL PROFESSION AS IT IS,
AND AS IT OUGHT TO BE.

Mr. Dermott's Second Letter to George James Guthrie, Esq.

DEAR SIR—My last letter contained observations upon the evidence given by you before the Parliamentary Committee, regarding the present constitution of the Council of the College of Surgeons, your objections to admitting general practitioners as members of the Council, and enfranchising all the members of the College, by giving them the power of voting in the election of members for the governing body.

To proceed farther—Sir A. Cooper literally states, "*that a person cannot teach anatomy properly unless he be an assistant-surgeon or surgeon to an hospital, and that the teachers of anatomy should be in every case connected with an hospital.*"

This is nothing else than the ghost of the obnoxious regulation of 1826, which pre-

cluded all medical men from being lecturers unless they were immediately connected with, or patronised by, an hospital, and which, in baseness, can only be compared to the "six odious acts of Castlereagh."

You, with most of the present examiners, very properly objected in evidence to this regulation; you stated that "the private schools ought to be protected," although, if all your suggestions were acted upon, they would infallibly have a tendency to crush those schools.

Sir Astley Cooper gives rather a strange reason for his proposition—it is this—"It is necessary," says he, "if I were lecturing upon any particular muscle or part of the human body, to cite some example, to show the utility of the knowledge of the part which I am describing; or else, were I to describe a muscle as arising at a part, or being fixed in another, nobody would attend to it; but, when I observed that inattention, I used to say, this muscle is placed close to an artery; that artery is liable to be wounded; you will see in such a ward, at this moment, a wound of that artery. Now, how would you find it? There is the muscle; you cut to the outer edge of the muscle." Do not, I would ask, private teachers do the self-same thing? I can answer for the majority in the affirmative; if it can be proved that a person does not, then he should in justice not be recognised. It has always been my particular object to mix up as much physiology and surgery with anatomy as possible, and to combine them as intimately as possible. To separate either the one or the other is artificial, and anatomy *in toto* loses its object.

We have yet to learn, my dear Sir, that private teachers* (improperly so called) cannot, both as a body and as individuals, describe surgical anatomy to pupils as well as the present disinterested hospital surgeons, who, you say, so philanthropically renounce money for the sake of virtuous fame.

We know that some of the latter never think of perplexing themselves much about anatomy, which, as a consequence, is in them rather rusty; and they are less acquainted than the majority of the lecturers in private schools with the most modern theories, cases, and experiments, owing to their being so enthralled, as they necessarily are, from morning to night, in their habitual routine of practice, in courting the aristocracy, the private friendship of the governors of institutions, &c.; for, after all, if the truth were told, such is the present bad and dishonest organization of the medical profession, that they principally depend upon the two last named means (together with money and family influence) for preferment.

We know, too, that many hospital surgeons, elected by private influence, have a

* Teachers who lecture *publicly*, but are not connected with hospitals.

bad foundation to start upon withal, and know quite little enough even as to theory.

If I mistake not, I recollect your stating, some few years ago, as an objection against an individual becoming hospital surgeon, that he was a teacher of anatomy, and that an anatomical teacher, to lecture daily and regularly, and do justice to his pupils, must devote the whole of his time to it. And, indeed, I believe it is impossible for an hospital surgeon, in extensive practice, to fulfil the duties of an anatomical teacher. On the other hand, as to the merits of private teachers, have they not, as a general rule, well studied their profession? Have they not raised themselves into repute amongst their professional brethren, and many of them realized success by sheer industry and talent, unbacked by patronage, in defiance of the flue walls, the glittering show, and the formal ceremonies of your public institutions?

You say, "that it has become a race to see how little money can be given, and how little can be taught for it; and, when the young man comes before us, we often find him incompetent upon those branches of knowledge which he ought to be acquainted with."

Does it follow that this is the fault of the teacher? Are all your pupils invariably competent? Are the deficiencies more glaring in the private schools than in the hospitals? As proof to the contrary, look to the printed report of rejections. You add, "the points in which he is found deficient, are not, perhaps, points so positively practical as to render him totally unworthy of being made a member of the College; and we do not like to refuse him, because his teacher has not taught him all that he ought to have done."—"With the support of due authority, it would be no longer a race between gentlemen, to see how little they would ask for the course of instruction; they would be obliged to ask a fair and reasonable sum, and, at the same time, they would be obliged to give a fair and reasonable course of instruction."

You do not mean to assert that, because they are cheap, they therefore must be invariably bad? If so, I do not envy your mode of reasoning. In reply, I would say, that however cheap, they would not be tolerated by a discerning profession were they not also good. But, as this allusion seems intended for the private teachers, and implicates their honour (their lectures being cheaper than the others, as a counteraction against the overbearing patronage and seductive appearance of public institutions), if you will accept a challenge, I will willingly make it, as to the quality of instruction given by the delivery of an anatomico-chirurgical lecture upon any subject, without preparation; the same to be drawn for by lots out of a vase, allowing me the choice of a place wherein to deliver the

same. I will engage, also, to compare pupils with you any day, both on anatomy and surgery.

Have not many of the private teachers been acknowledged, by the Council of the College, again and again, to be good practical teachers of anatomy?

Sound theory is the best directing post to correct practice. It is the head which should direct the hand of the physician in prescribing; that of the surgeon in operating, as well as the tongue of the lecturer or examiner in explaining or interrogating. Is not a learned theorist (whether a public or private teacher) likely to make a more celebrated and safer practitioner, and a better lecturer too, than some thick-heads, who, without a single original idea in their brain-case, or a single just pretension to public favours, were born in an atmosphere of preferment, with plenty of money to back them, and who are just able, in consequence of purchased opportunities and dint of habit, to go through a daily and commonplace course of surgical manipulations? Are not those men who have taken pains to possess themselves of theoretical knowledge, or the experience of others, as well as in some degree of their own, much less liable to make egregious practical blunders in surgery, or medicine, than the persons comparatively unfurnished with it? Moreover, is it not a correct opinion, founded upon sound theory, the offspring of observation, either of himself or others, conjoined with the natural faculty of communicating ideas, which gives capability both to the lecturer and examiner? A man who has had a regular professional education, can always form his judgment to a certain degree from his own experience, conjoined with that of his contemporaries and predecessors; and every man who has thoroughly studied his profession ought, in justice towards himself and society, to have an opportunity of practically applying his knowledge for the good of the public. And if the system regulating the profession is such as to prevent him so doing, that system must be bad.

The real state of the case, at present, stands thus:—An hospital surgeon has an apprentice (perhaps his relation), the latter become so by purchase—say a thousand pounds—or by his relationship. He subsequently pays a sum of money to become a dresser; afterwards, another large sum to be house-surgeon. Next, by paying another sum of money, he becomes a governor to the hospital, perhaps for life. If he is an intriguing man, he takes care in the meantime to cultivate the private friendship of the main body of the governors by every means in his power. A vacancy now occurs for the assistant-surgeon, and if he has been so fortunate as to have kept on good terms with his former master, he is strongly recommended to the governors (*pro formâ*)

as having a claim upon the institution, in consequence of having occasionally officiated voluntarily as house-surgeon during the absence of the latter. He upon these grounds generally succeeds; but sometimes money has to step in again, and put the finishing stroke to it. Many have entered hospitals in this way, and some may be now in a state of expectancy to do so; but it would be invidious to mention names. I have to contend with principles, not with persons. It has been argued, that if the governors and hospital surgeon find his apprentice or relation as well qualified as the rest, he has a right to give him the preference; but, I would ask, may not the hospital surgeon be biassed in favour of his apprentice or son? Are the governors, non-medical, able to judge of the comparative medical merits of the individual? Are any of them capable of judging of the merits of other persons, of whom they have never heard, and whom competition has never called forth? Perhaps you may say, that the public hospitals are invested property. My dear Sir, you may as well talk about the lives of the patients in them being invested property: if you make it a mere property question, away with the term "charity" *in toto*.

The comparative merits of private and public teachers, and of some private and public servants, will soon, perhaps, be tested in a way not hitherto done in England, and which may be consequently novel and surprising even to you.

I remain, my dear Sir,

Your obedient servant,

G. D. DERMOTT.

Medical School, Gerrard-street, Soho.

August 12th, 1835.

Hospital Reports.

WESTMINSTER HOSPITAL.

Extensive Malignant Disease of the Mammary Glands ("Tissu Lardacé")—Necropsy.

A FEMALE who had passed the meridian of life, and was of a very corpulent habit, and who had formerly been a patient of Mr. White's at the old hospital, with what was supposed to be a fungous disease of one of the breasts, was recently admitted into St. Ann's ward. Since she left the hospital she had been under the care of some advertising empiric. The disease, however, increased rapidly, and extended to the other breast. At the time of her re-admission the two breasts had attained an immense size, much greater than is generally seen in cases of true scirrhus; they approached each other over the median line of the body, and appeared to communicate, by the extension of the disease, with the axillary lymphatic

glands. The integuments covering this immense mass of disease superimposed over the thorax, was of a livid colour, and tuberculated by the presence of nodules, of various size, in its tissue. From the pressure of the tumours on the lymphatics and veins of the arms and neck, the upper parts of the body, and the arms more particularly, gradually became anasaruous, excessive dyspnoea came on, and she was evidently passing quickly into the last stage of the disease. Mr. White, on one occasion, made numerous punctures with the point of a lancet in the back of the hands and the surface of the mammary tumours, from which a large quantity of serum was for several days discharged. This little operation relieved her a good deal, for a time, of the dyspnoea.

The relief thus obtained, however, was only of temporary benefit; the dyspnoea became rapidly augmented, and amounted to orthopnoea; the countenance indicated the severest distress; she sat up in the bed leaning forwards, with her chin on her knees, in order to give the greatest power to all the accessory respiratory muscles, and had two women by her side, almost constantly engaged in fanning the air towards her. She was perfectly sensible and collected, and aware of her approaching death, of which she spoke with calmness. After existing in more or less of this distressing condition during two or three days, death at last put a period to her sufferings.

Necropsy.—The mammary glands were found imbedded in a quantity of dense yellow fat, and upon making a vertical section through them, they were found enlarged to two or three times their natural size, consisting of a semi-transparent whitish tissue, with here and there a yellowish fibrous-looking tissue, traversing the general mass of the tumour. The general appearance of the mass seemed closely to correspond with the description given by the French pathologists, of a variety of malignant disease, which they denominate "tissu lardacé," or "pork-like cancer," from its resemblance to the boiled fat of pork or beef, and of which Dr. Carswell has given some good representations in his "Illustrations of Morbid Anatomy." This distinguished pathologist makes this form of heterologous formations a variety of his species scirrhus, which includes all those forms of malignant disease which do not possess an independent vascularity of their own.

The diseased masses of gland communicated, especially on the right side (the breast of which was most extensively diseased), with the axillary gland, the tissue of which had undergone a corresponding alteration. In the course of the fibres of the pectoral muscles, numerous small white granular bodies were met with, not larger than a millet seed, and which appeared to consist of a tissue analogous to that of which the breasts were the seat. The tubercles which existed

in the skin were hard, firm, and yellowish, resembling true scirrhus.

In the cavity of the pleura of the left side was a quantity of serum, between two and three pints. The pleura of the right side was adherent. The lungs were in a state of severe oedema, being gorged with a quantity of sanguinolent serum. The heart was of a flabby consistence, but in other respects appeared quite natural. Both the liver and spleen were in a highly congested state, and so soft as to be ready to break down under the pressure of the fingers. The other abdominal viscera did not present, so far as they were examined, any traces of disease.

—o—

Foreign Medicine.

Physiological and Pathological effect of Drunkenness on herbivorous and carnivorous Animals. By M. Pommer. Inserted in the Schweizerische Zeitschrift für Natur und Heilkunde.

IN this memoir the author endeavours to shew to what degree drunkenness may be carried in animals, the physiological and pathological effects, and the deduction to be made with reference to that state in man. He relates in detail fourteen experiments made on dogs and rabbits with spirit from grain. In some of the animals the fluids was introduced into the stomach by an elastic gum tube; in others it was directly injected into the veins at various distances from the heart; the doses of it were gradually increased. Dogs resisted the effects of brandy for a longer time than rabbits; the latter died in from forty-eight to fifty days at the latest, after drinking three pounds and some drachms of it. The first symptoms they exhibited were of short duration, and were not appreciable before the forty-second day, when each one received an ounce of spirit night and morning. The dogs, on the contrary, who appeared to be drunk as early as the twentieth day, with half an ounce of the liquor twice a-day, did not die until towards the seventy-second day, after taking seven pounds and a half of alcohol.

Of the animals in whom the spirit was injected into the veins, some died immediately, others survived somewhat longer, according as the injection was into the jugular or saphena, and with more or less fluid. The symptoms are chiefly characterized by uncertain movements, a tottering walk, insensibility, and coma. Shortly after the paroxysm, the animals again become alert, and devour food with avidity. Generally speaking, their appetites remained good to the last. In them drunkenness never commences with gaiety, as in man. At the height of the fit the beatings of the heart slackened; when dogs could vomit, their drunkenness was neither so strongly pronounced nor so long. Rabbits could never vomit. Notwithstanding their

voracious appetite, the animals grew very thin during the time of the experiments. The breath never gave out that peculiar odour observed in drunkards, and no means could detect alcohol in any humour or secretion. Blood drawn from the jugular veins, cerebral sinuses, and other vessels, before and after death, never exhibited any alcoholic odour, and in no way differed from that of other animals.

Dissection disclosed no lesion that could be attributed to alcohol; only in animals immediately killed by the injection of it into the veins, the blood had an alcoholic odour.

From all these experiments, which were made with the utmost precision, the author concludes that the abuse of alcoholic liquors may kill, but that they do not act on the system by absorption, and their primary effect is a vehement impression the nervous system.

Upon the above notice, the editors of the *Gazette Medicale* observe—"There is not much novelty in these experiments of M. Pommer. We must also deny his assertion that the presence of brandy cannot be detected in the blood of animals that have had injections into the stomach; the fact is certified by M. Deyber, of Strasburg, in the following manner. A cow who had had two drachms of a spiritous fluid, administered by a veterinary surgeon, was shortly after killed: nothing was at first observed, except some little phlogosis along the esophagus. The meat of it was distributed to several families, and had a good appearance; but, as some said, also a bad taste. On cooking some of the meat himself, M. Deyber was surprised to find that it gave out a decided smell of ether, which it did not possess in the crude state. When ingested in morsels or in soup, the meat left a strong taste of ether in the throat for some hours."

The Guaco.

This plant is in considerable vogue in many parts of South America, for many complaints, but more especially for the bite of mad dogs and venomous serpents; latterly it has been employed with success in cholera. It belongs to the family of synanthérées, the tribe of corymbifères and section of eupatoriæ; and is met with in the province of Santa-fe and in Brazil; it is a climbing plant. To form a decoction of it, two drachms of the stalk and half a drachm of the leaves are to be boiled for several hours with three pints of water reduced to two; the same wood will serve for two boilings; the decoction is bitter. The tincture of guaco is prepared, as other tinctures are, by infusion; its colour is green. The dose of the decoction is from one to four ounces. If it causes thirst, epigastric pain, and red tongue, it should be freely diluted with water. If insupportable by the stomach, it should be given in glyster.

Fluids for the Preservation of Dead Bodies.

The following is M. Breschet's resumé of the objections that may be raised against the various liquors that have been used for this purpose. It occurs in his report on M. Gannal's proposition for a new fluid, made to the Académie de Médecine.

The requisites for such a substance, says M. Breschet, are a low price, easy carriage, and small volume, for researches made at great distances.

Now, alcohol is too dear, is only fit for small bodies, is not easily conveyed, evaporates rapidly, especially in hot climates, and dissolves the resins that stop the mouth of the vessel. Joined with acids, it softens the bones, destroys the colours and tissues, and rapidly oxidizes the dissecting instruments. The same occurs if it contains arsenic or corrosive sublimate in solution.

Oil of turpentine is only fit for small preparations, alters many of the tissues, and becomes thick and turbid.

Oils only preserve certain fishes; their price is too high, and they are not always to be got.

The syrups that are proposed for preserving the brain and spinal cord are too dear in large quantities; they do not penetrate the tissues, and deposit crystals on the surface, or a viscid matter, which ruins the colours; in warm climates they ferment.

Creosote, which is recommended for the preservation of the brain and nerves, is also too dear; moreover, its action on the general tissue is not yet ascertained.

Sea salt is altogether inadmissible, and its insufficiency undoubted.

The chlorurets of the oxides of calcium, sodium, and potassium, have been recommended, but are unequal to the preservation of slightly thick masses, still less of entire animals.

Wine added to a nitrous solution of mercury, cannot be used in great quantities.

Acids attack the tissues and instruments.

Aqueous or alcoholic solutions of the salts of mercury, and arsenical solutions, are dangerous, from their emanations and long-continued contact; they harden the tissues, alter their colours, and harm the dissecting instruments.

Pyroligneous and acetic acids also attack the organic tissues, and corrode them, and withdraw the earthy matter of the bones, which they render flexible and transparent, while they cover the soft parts with a glutinous layer, which conceals their structures and the fibres.

Alum and nitrate of potash in watery solution have been employed by anatomists; sausage makers use saltpetre to preserve the fleshy tissues and give them a vivid red.

M. Gannal's liquid is composed of two parts of supersulphate of aluminum and potash, and of chloruret of sodium, and one part of nitrate of potash.

In a fluid thus made, two dead bodies were kept for two months, at the end of which time they had not changed appearance, and were readily dissected and served for anatomical demonstration. It remains to shew how long it will actually preserve bodies; what temperature it can resist; the expense of it; whether it can be employed to bring home from distant parts large zoological specimens, &c. &c.—*Gazette Medicale*

GRADUATIONS IN MEDICINE AT THE UNIVERSITY OF EDINBURGH.

THE following gentlemen, 117 in number, received the degree of Doctor in Medicine at the close of the session of this University, on Saturday, August 1:—

OF SCOTLAND.—Arthur Anderson, on Absorption; John Arnott, on Erysipelas; James Anderson, on Continued Fever; George William Bell, on Delirium Tremens; Walter Scott Carmichael, on Phthisis Pulmonalis; William Carson, on the Pathology of Phlegmatia Dolens; George Chaplin Child, on Injuries of the Head; James Cornwall, on Excision of the Joints as a substitute for Amputation; James Cox, on Morbid Poisons; Samuel Currie, on Aneurism; James Dunsmore, on Scarlet Fever; Thomas Duncan, on Animal Heat; Andrew Ferguson, on Hepatitis; David Deas Foulis, on Phlegmatia Dolens; Alexander Harvey, on the Function of Nutrition; William Home, on Acute Anasarca and Diseased Kidney; Henry Johnson, on Pleurisy; James Townsend Oswald Johnston, on Ophthalmia; Thomas Glen Johnston, on Erysipelas; William Woods Johnston, on Acute Peripneumonia; George King, on the Pulse; Kinloch Winlow Kirk, on Superfoetation; William Kirkland, on Hydrocele; Andrew Cairncross Livingston, on Acute Hydrocephalus; Thomas Macnight, on Expectoration; Duncan Macpherson, What are the Agents concerned in Capillary Circulation? Andrew Millar, on Erysipelas; George Thomson Mitchell, on Tetanus; David Monro, on Aneurism of the Thoracic Aorta; Donald Monro, on Angina Pectoris; John Kinloch Ogilvie, on Morbus Coxarius; Alexander Peddie, on Erysipelas; John Hunter Pollexfen, Orkney, on Peritonitis; James Ramage, on Adhesion of Wounds; John Spens, on Rheumatism; John Thomson, on Peritonitis; William Troup, on Stricture of the Urethra; Thomas Graham Weir, on Hydrocephalus and its Treatment; William Wood, on Diseases of the Female Breast.

[Those from England, Ireland, and abroad next week.]

LECTURES

ON THE

INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXVI.

Physiology of the Respiratory System of Nerves—Volition as a Stimulus to Irritability.

AMONG the minor effects of a section of the pneumogastric nerves will be of course a loss, more or less entire, of the voice, and a corresponding want of change in this function from emotion. The pneumogastric nerve, regarded as respiratory, seems to stand in the same relation to the larynx as the pathetic nerve does to the eye-ball, and the facial nerve to the features of the face; but with respect to the pneumogastric nerve in this part of its distribution, the same remark may be made as has been already made with respect to the facial nerve in its distribution on the face, that as the pneumogastric nerve is not only a respiratory nerve, but the only or chief motiferous nerve with which the muscles of the larynx are supplied—as will be explained in future—the want of change in the voice from emotion, after a section of this nerve, proves nothing in favour of the presumption that it is by the respiratory nerves that the stimuli of sympathy and passion or instinct are conveyed. With respect to the division of the spinal accessory nerve, this has been found to cut off all sympathy between the lungs and muscles of the neck and shoulders, as well as all effect on these muscles of emotion, so that they no longer act under either the most violent impediment to inspiration, or the most intense mental perturbation, although the animal can still call them into play by volition. And it is thus that in asthma, which appears to consist in a defective conveyance, by the pneumogastric nerve, of the natural stimulus of sympathy, these muscles are excited, not involuntarily by this natural stimulus conveyed to them by the accessory nerve, but with great efforts by the stimulus of volition conveyed to them by numerous motiferous nerves with which also they are supplied. This fact furnishes a beautiful illustration of the different functions of the respiratory and motiferous nerves, particularly if taken in conjunction with the converse fact that in palsy—which affects the latter only—while the animal is now incapable of calling these muscles into action by volition, they continue to be excited as usual by every impediment to inspiration and by every violent mental emotion. Again, the division of the phrenic nerve of course prevents the diaphragm from taking any part in inspiration as excited by sympathy, as well as puts a stop to all the other numerous sympathies in which this organ is naturally engaged. Thus, with respect to its *active* sympathies, there is no longer any gasping from cold applied to the face, any vomiting from a mechanical irritation of the fauces, nor any hiccough from an affection of the stomach; and with respect to such as are *passive*, an irritation of the diaphragm no longer excites the convulsive descent of the lower jaw, as in yawning. It is indeed in all probability by at once paralyzing the whole respiratory system of nerves from the violent shock communicated to the phrenic, and thus shutting up, as it were, the fountain of all the sympathetic actions of the body, and not, as is commonly supposed, by any impression made on the celiac ganglion, that a violent blow on the pit of the stomach is sometimes so suddenly fatal (a). Lastly, a division of the ex-

(a) "A blow on the pit of the stomach," as remarked by Sir Charles Bell, "doubles up the bruiser, and occasions the gasping and crowing which sufficiently indicate the course of the injury—a little more severe,

and the blow is instantly fatal. A man broken on the wheel suffers dreadful blows, and his bones are broken, but life endures—the coup-de-grace is a blow on the stomach."

ternal respiratory nerve prevents, of course, the co-operation of the muscles on the sides of the chest with those of the neck and shoulders during either impeded respiration or violent mental emotion. Upon the whole, then, it appears that the result of direct experiments by which the several respiratory nerves have been obstructed is decidedly favourable to the doctrine that they are the vehicles of sympathy and passion, or instinct, since the conveyance of these stimuli is for the most part at once intercepted by such obstruction.

The foregoing, then, are the chief arguments which can be adduced in favour of the hypothesis in question; the principal objections to it, on the other hand, besides the commonly believed circumscribed distribution of the respiratory system of nerves, and the alleged impossibility of tracing them all to any common origin—both which objections have been already replied to in passing—are, first, that many of the most remarkable instances of sympathetic action take place when, upon the presumption that the immediate stimulus by which these actions are excited is conducted by the respiratory nerves, we should not have expected them, while, on the contrary, such actions are sometimes quite wanting when, upon the same presumption, they would appear to be unavoidable; and, secondly, that not a few of the nerves above assumed as nerves of involuntary motion are pretty certainly nerves of voluntary motion and even of sensation.

There is, it may be observed, no immediately obvious connection by large or numerous respiratory nerves between the female genital organs and mammae, between the diaphragm and lower jaw, or between the schneiderian membrane or that lining the glottis and abdominal muscles, and yet no parts more intimately sympathize with each other than these; while, on the contrary, the connexion by such nerves is most direct and conspicuous between the glottis and gullet on the one hand, and between the lungs and stomach on the other, and yet these organs offer comparatively very obscure indications of mutual sympathy. It implies, however, a very inadequate conception of the principles of the doctrine in question to look for any direct connexion by respiratory nerves of organs sympathizing with each other, as if the stimulus were to be conveyed *immediately* from the one to the other. It is a fundamental principle of this doctrine that every sympathetic connexion between the various organs is through the medium of the respiratory tract, or common root of all the nerves of this system; and in this view of the matter perhaps all the organs of the body are almost equally connected together by the respiratory system of nerves. But why, then, it may be asked, should not all the organs of the body sympathize equally with any one in a state of primary irritation, instead of some certain organs only being thus involved? In order to understand this, we must keep in mind that every organ of the body has its own specific character of irritability, and undergoes, therefore, on the application of any stimulus, a specific kind of irritation; which irritation now become a secondary stimulus, although conveyed perhaps indiscriminately to all the other organs of the body, will nevertheless act only or chiefly on those to the specific irritability of which it is adapted. The size or number of the respiratory nerves sent from the common root of all to each part may, perhaps, be a measure of the *quantity* of stimulus sent to this part in every case of primary irritation at a distance; but of its *quality* we have no measure, any more than of the *quality* of the irritability of the part to which the nerves tend; and we must never forget that two conditions are essential to every vital action—namely, a specific stimulus to act and a specific susceptibility to be acted on. We must not calculate, then, upon the quantity of stimulus alone, when the quality, not only of this, but of the irritability, may be such as at one time to give rise to very violent effects from the slightest degree of stimulus, and at another to counteract any effect from the most considerable. A small spark falling among combustible matter excites a violent commotion, and a few grains of mercury introduced into the system act forcibly upon the salivary glands; but an intense flame plays without effect on incombustible materials, and a bushel of mercury thrown into the body does not affect organs to the specific irritability of which it is not adapted. Upon these principles it is easy to understand the fact which has been before alluded to, that one kind of primary irritation of the lungs acts on the expiratory, and another on the inspiratory muscles. The nerve conveying these primary irritations to the common tract is in both cases the pneumogastric, and each traverses afterwards the sum of all the nerves connected with this common centre, and that more or less copiously, perhaps according to their size and number; but it displays its effects, not indiscriminately on every organ in proportion to the supply of this stimulus, but on that set of muscles alone, whatever be the supply, the specific irritability of which is alone competent to acknowledge it. It is hence obvious that while no fair objection to the hypothesis in question can be founded on the want of correspondence between the more or less conspicuous connections of parts by means of respiratory nerves, and the greater or less manifestation between these parts of a mutual sympathy, the incorporation of them all, through the medium of a common root, into one universally diffused system, by no means involves as a consequence the indiscriminate participation by every organ in the primary irritation of every other.

Again, it is true that some of the nerves above enumerated as respiratory, or subservient to involuntary motion, are likewise the instruments of voluntary motion, and even

of sensation, to the parts on which they are distributed. There are no organs, for example, over which we have a more decided control, under ordinary circumstances, than the muscles of the face and those of the larynx; yet the former are supplied, as an instrument of voluntary motion, only with the facial nerves, and the latter only with branches from the pneumogastric. But this circumstance, so far from militating against the hypothesis in question, serves rather to confirm the justice of its principles; for each of these nerves, although derived mainly from the respiratory tract, receives at its origin, as has been already remarked, some filaments from the corpora olivaria, which, as immediately connected with the anterior columns of the spinal cord, may be presumed to impart to it the power of conveying the stimulus of volition, while all the rest of the nerves conveys only the stimuli of sympathy and passion, or instinct; and, accordingly, this motiferous portion of the cylinder may sometimes act independently of, or even as an antagonist to the other, as happens, on the one hand, when we counterfeit the effects on the features and voice of a passion which we do not feel, and, on the other, when we conceal such effects of an emotion by which we are actuated—or even, sometimes, combining simulation with dissimulation, not only constrain the expression of one passion, but substitute for it that of another of a diametrically opposite character. Nor is it only by additions made to them at their origins, that the so called respiratory nerves may become qualified in their character, since most of them are united in their course with nerves coming from other systems; so that what was at first a simple respiratory, or a combined respiratory and motiferous nerve, may become at length of a very complicated character. Thus the facial nerve, after emerging from the parotid gland, is united with filaments from the sensiferous portions of the trigeminus, so that, in its subsequent course, it is so far from a simple respiratory nerve, that it possesses a triple character (*a*)—nay, combined, as it may be presumed to be, like all the other cerebro-spinal nerves, with filaments from the ganglionic system, it perhaps plays at last a quadruple part (*b*)! And it is thus perhaps, as already stated, that we must explain the occurrence of the ganglions, before alluded to, on some of the chief branches of the respiratory system of nerves, and, in particular, the pneumogastric; such ganglions—which have served to throw still further ambiguity on the nature and office of these nerves—belonging probably not to them, regarded as simply respiratory, but to some of the other nerves with which they have become associated. The probability of a mutual interchange of filaments wherever nerves of different systems unite together, is too great to allow us, when speaking of any individual nerve, whether of the respiratory, or any other system, to assume that it is to that system that it exclusively belongs, every reputedly ganglionic nerve, for example, comprehending perhaps some respiratory, some motiferous, and some sensiferous filaments; every reputedly respiratory nerve, some ganglionic, some motiferous, and some sensiferous, and so forth, although each nerve is, with propriety, regarded as belonging more peculiarly to that system from which the greater number of its filaments seems to be derived, and to the proper function of which it appears to be in a more particular manner subservient. The objection, then, to the hypothesis which regards the respiratory nerves, *qua* respiratory, as the vehicles of sympathy and passion, or instinct, founded on the complex functions to which some of these nerves, taken collectively, appear to minister, cannot, any more than the one already disposed of, be fairly sustained.

In conclusion, we seem warranted in believing that the office above assigned to the respiratory nerves is the one which they really perform in the animal economy, particularly when we find it impossible otherwise to explain why almost every organ of the body should derive its nerves from sources so very different. Thus all the motions of the eyeball, involuntary and voluntary, might have been performed without the pathetic nerve, all those of the face without the respiratory portion of the facial, all those of the tongue without the glosso-pharyngeal, provided only Nature had supplied each of these organs with a few additional nerves from the motiferous system; and this she would unques-

(*a*) It was accordingly found by Mr. Broughton (Mem. read to the British Scientific Association at Edinburgh, 1834), that a stimulus applied to the facial nerve, anterior to the parotid gland, excited, in addition to twitches of the muscles, &c., symptoms of acute pain, although no such symptoms manifested themselves when it was irritated within the substance of the gland.

(*b*) The probability of this complication in the office of the several nerves, owing to the union in each of the filaments coming from distinct systems, is very explicitly ad-

mitted by Sir Charles Bell himself. Speaking of the different actions performed at different times by the facial nerve, and as he then supposed by the trigeminus also, he remarks, "It remains a question, whether these different actions do not depend upon the influence of distinct filaments of which each nerve is composed. I believe," he adds, "that these nerves consist in a great measure of distinct filaments bound up together, and analogy would lead me to suppose them capable, therefore, of distinct functions."

tionably have done, had not all these parts been destined to be acted upon, either constantly or occasionally, by stimuli distinct from that of volition, and to the conveyance of which the motiferous nerves were inadequate. At the same time it must be conceded, that there are many points in this hypothesis which require further investigation, and that it is probable that such investigation will detect in it many mistakes and oversights: but was it to be expected that so bold and comprehensive an hypothesis should be, from the first, without spot or blemish—without any errors to correct, or gaps to fill up? If it appear, upon a cool and patient review of the whole question, to be substantially correct, let us not immediately reject it because certain points in the detail require corroboration, but assume it to be at least generally true till it is proved to be otherwise, upon the principle already insisted upon, that any opinion in physiology, which has been deliberately taken up upon the best evidence which we can at any given time command, is always preferable to no opinion at all. Such an opinion not only gives the mind the temporary relief which is essential to renewed efforts, but by furnishing it, not so much with a haven in which to cease for ever from labour, as with a starting point, whence it may take another sweep, often conducts it by a comparatively short route to conclusions at which, by floundering on for ages in a sea of conflicting and unarranged facts, it could never by any possibility have arrived. Let us have upon every point an axiom, if we can get it; if not, a theory; if not, at least an hypothesis; but let us always have something upon which we may proceed; taking care, in the mean time, to attach to our doctrines no more credit than they severally deserve, and being always ready to modify or to discard them when we meet with facts which are not reconcileable to them as they stand. It may be somewhat irksome to be thus continually untying our faggots and binding them up anew, perhaps from a single stick having become loose; but it is infinitely less so than to be lost from the first and for ever in a chaos of such sticks without any arrangement at all. If the tendency to systematize on few and ill-established facts is vicious, the propensity to accumulate facts, without referring them to any system at all, is at least equally so: true philosophy consists not in separating, but in combining the two—in regarding speculations as valuable only in as far as they are founded on facts, and facts as no further useful than in as far as they are susceptible of some generalization.

In regard to the *manner* in which the stimuli of sympathy and passion, or instinct are conveyed—whatever be the *channels* through which they pass—we are almost entirely in the dark. In speaking of the ganglionic nervous tissue as the seat of irritability, the latter was described as a property with which this tissue becomes endowed in virtue of its peculiar aggregation; and, in conformity with this view, we must regard the nerves by which the stimuli in question are conveyed as the seat of these stimuli, considered not as entities, but merely as powers with which they become endowed likewise in virtue of their peculiar aggregation. But such powers are not—at least very obviously—constantly in operation, nor, therefore, constantly in existence; for the other condition of vital action—namely, irritability—being always, we may suppose, at hand, wherever no action takes place, we have a right to infer that the power which should excite it is wanting. Hence it results that, in order to develop this power, the nerves in which it is resident must undergo some molecular change, as a consequence of the primary irritation which they are to extend to distant parts, similar to that which they undergo from a direct chemical or mechanical stimulus; and that it is in virtue of this change in the nervous matter throughout all its ramifications that such distant parts become involved, such nervous matter now acting on those parts in the same manner as any direct stimulus acts on those which are the seat of a primary irritation. Of the nature of this molecular change, however, we are utterly ignorant: it is in all probability entirely *sui generis*, and such as cannot be illustrated by a reference to any thing out of the body—we recognise this change only by the powers which it develops, and we recognise those powers only by their effects (a).

(a) At the time when it was customary to regard every kind of nervous energy, as it is called, or stimulus conveyed by the nerves as substantial—as much so as the air which we breathe, or the aliment which we swallow, in conjunction with which the passions, one variety of this nervous energy, were enumerated among the non-naturals—it was usual to represent it as a kind of fluid, and to explain the transmission of such nervous energy to distant parts upon the presumption of the flow of such fluid along the nerves. Dr. Mason Good accordingly states, that it is for the purpose of “elaborating this exquisitely fine and active fluid,” that the

brain is glandular in its construction; and it is because we require a fluid of very different qualities on different occasions, that the nervous system is of so “composite” a “fabrication!”—(Study of Medicine, 1825.) The advocates of this doctrine, however, have unfortunately omitted to adduce any kind of evidence, either of the existence of this fluid, or of its competency to explain any of the phenomena ascribed to it, while, on the other hand, its admission brings with it many more difficulties than it removes. Without this admission we have merely the difficulty of explaining the nature of the molecular change which the nervous matter

The last of the stimuli, by which irritability may be excited, and, which like sympathy and passion, or instinct, is likewise an indirect one, is volition. Like passion or instinct also, volition, regarded as a stimulus to irritability, consists in a translation of a direct or primary irritation of the brain to any other organ; and, in this view of the matter, volition, as well as passion or instinct, may be represented as merely a variety of sympathy, and as constituting a second department of what is called *animal sympathy* in contradistinction to *organic*. As, however, passion or instinct, and reason, including volition, are, with propriety, regarded as two very distinct modes of thought, and as the latter, acting as a stimulus to irritability, appears to be translated by a system of nerves quite distinct from those by which the former is conveyed, it was proper to treat of them under distinct heads, and while the consideration of passion or instinct was incorporated with that of sympathy in general, to speak of volition *per se*. It is hardly necessary to repeat here, that the irritation of the brain, in which volition originates, is not, any more than that which gives rise to passion or instinct, absolutely direct or primary, such irritation being necessarily preceded perhaps—as will be explained in future—by sensation, as such sensation is by irritation of some other part; contemplating volition, however, merely as a stimulus to irritability, we begin with this irritation of the brain, without reference to any conditions on which it may be dependent (*a*). And that such a stimulus to irritability exists is sufficiently manifest. We all know that when we wish to bend the finger the flexor muscles of this part are immediately called into action. This wish cannot have produced a direct irritation of any

itself may be presumed to undergo when it is to develop the power in question; whereas, with it, we have to explain first, by what process this fluid is formed; next, by what powers it is moved forwards; and, lastly, by what means nerves which, though fibrous, are not tubular—and if their fibres are composed of filaments, the ultimate structure of which is globular, it is impossible that they can be so—can transmit it, as well as why, when tied, they do not, like an obstructed blood-vessel, become turgid on either side of the ligature. The last difficulty may indeed be got over by presuming that the fluid in question is of the nature of caloric or galvanism, and, therefore, neither requires that the nerves should be pervious in order to conduct it, nor is capable of rendering them turgid if obstructed in its course—and we know, in fact, that such nerves do act as conductors of galvanism. Against the doctrine, however, that the nervous energy is *identical* with galvanism, it has been already contended at sufficient length, and the doctrine that it is a fluid at all *allied* to it is destitute alike of proof and probability. Opposed to this doctrine of the substantial nature of the nervous energy in the form of a fluid, was that of Hartley (On Man, 1749), and Darwin (Zoomonia, 1794), who imagined that it consisted in vibrations excited in the nerves, and that it was thus communicated from one part to another. A similar doctrine had been before promulgated by Glisson and Malpighi, to explain the nature of the influence communicated by the nerves in giving rise to sensation, such nerves being represented as having been previously rendered sufficiently tense to admit of vibrations by the influx into them of a certain "*succus nervosus*" supposed to be secreted by the brain; so that, although this supposed fluid was no longer regarded as *per se* constituting the nervous energy, it was still considered necessary to its development. The hypothesis

of Hartley and Darwin differed from that of Glisson and Malpighi, principally in as far as they applied it to explain motion rather than sensation, and represented the course of these vibrations as rather from the origins of the nerves towards their extremities, than in the opposite direction: in effecting the proper sympathetic motions, however, such vibrations, if they took place at all, would have to proceed first in the latter direction, and afterwards in the former. But against this doctrine of vibrations *in toto*—not to recur to the imaginary nervous fluid as instrumental to them—it may be objected that none of the nerves have either the hardness, the tension, or the freedom from contact necessary to this condition; and though this doctrine is less exceptionable, perhaps, than that which represents the nervous energy as an entity, it is still very wide of the mark, and worthy of remembrance only as furnishing a good example of the common reproach of physiologists, of endeavouring to identify processes which every view of the matter might induce us to regard as molecular and peculiar to living matter, with others with which, as obvious to the senses, and as displayed by dead matter, we are more familiar. We should never forget that

— *Extremum cuiusque cacumen*

*Corporis est aliquid nostri, quod cernere sensus
Jam nequireunt;*

and when we cannot exalt our capacities to the comprehension of vital actions, it is much better to say so, than to endeavour to bring down these vital actions to the level of our capacities.

(*a*) It would be as improper as it is unnecessary to enter at present into any discussion on the abstract nature of volition, as a department of reason—a subject obviously belonging to the head of Thought. It may be spoken of as a stimulus to irritability, like all the rest, without any regard to its essential character.

part, except of that which is the immediate seat of volition, but the muscles so called into action must, nevertheless, have been subjected to some stimulus, or they would not have acted; and it is this translation of a primary irritation of the brain, distinct from that in which passion or instinct consists, to distant organs, which is understood by volition in its character of a stimulus to irritability.

The examples of the operation of volition in this character (*a*) are much less numerous than those of the action of sympathy and passion, or instinct; the former being confined principally to the external muscular tissue, or that constituting the muscles which enter into the composition of the containing parts, which are for the most part attached, directly or indirectly, to the skeleton, whether connected or not with the mucous membrane, and the action of which is always sensible, while the latter is not only exercised on this, but is extended likewise to the internal muscular tissue, or that constituting the muscles which enter into the composition of the contained parts, which are unconnected with the skeleton and generally in contact with mucous membranes, with the exception of the heart, the parenchymatous tissue, and the irides, and the action of which is not only sensible but molecular. Accordingly, volition is perfectly powerless as a stimulus to the heart, the action of which is so much under the influence of sympathy and passion; as well as to the capillary vessels, so that it never gives rise, as they do, to either blushing or paleness of the cheeks, refulgence or dullness of the eyes, turgescence or flaccidity of the clitoris or penis, the fimbriæ of the fallopian tubes, the nipples of the mammæ or other erectile organs, and has no influence, like them, on the secretion of the halitus from the lungs, the gastric fluid, the intestinal gases, the menstrual fluid, the fat or the sweat, the mucilage, stools, or sebaceous matter, the bile, milk, semen, tears, or saliva. Further, volition is quite inert with respect to the stomach, and the muscles by which vomiting is effected, over the actions of which both sympathy and passion exercise so much control, as well as with respect to the uterus, the action of which is so easily influenced by passion, and, among the organs of sensation, with respect to the iris, the motions of which are effected perhaps exclusively by sympathy (*b*). On the other hand, volition is quite competent to effect or control many of the motions which, under ordinary circumstances, are excited and regulated by sympathy and passion, or instinct alone. It is thus that in some cases of impeded respiration, for example, asthma, originating as it appears to do in an affection of the respiratory nerves, volition appears to stand in the place of sympathy, or even instinct, although its influence, extending only to a few of the respiratory muscles, and these not very effective ones, it performs its part not only with great effort, but very inadequately. It is at all times, however, in our power to control, to a certain degree, the natural respiratory process by volition; and this we constantly do under the various circumstances of speaking, singing, playing on wind instruments, violent efforts of every kind, and innumerable other occasions; it is only, however, within certain limits that we can do this, the natural stimulus to respiration becoming after a time too powerful to yield to any exercise of volition, so that no man can voluntarily asphyxiate himself.

So also the actions of the various muscles by which sighing, yawning, hiccupping, sneezing, groaning, screaming, sobbing, laughing, and coughing, are severally effected, although commonly excited by sympathy and passion, or instinct, may be excited also

(*a*) It is almost superfluous to say that plants, in all probability, perform no actions corresponding to the voluntary motions of animals. If plants are destitute of sensation, they must *à fortiori* be destitute of every modification of thought—but this subject will be resumed in future.

(*b*) Some extraordinary cases have occurred in which the heart and stomach have appeared to be voluntary muscles—the former, in the remarkable case of Colonel Townsend, related by Dr. Cheyne (English Malady, 1734), and in another recorded a short time ago by Ribes, the latter in the numerous cases on record in which persons have been capable of ruminating or vomiting at will. It is probable, however, that it was not volition which in these cases immediately operated on the organs in question, but passion, their possessors having been capable, by the force of imagination, of exciting the requisite emotion at pleasure. Many persons can blush and make their eyes

sparkle, all can produce a turgescence of certain organs, and not a few can shed tears when they choose to do so; but it is not volition which immediately excites these actions, but the emotions which volition has called into existence. The phenomena of animal magnetism furnish many illustrations of this principle; but to these it is unnecessary to refer at present. At the same time, there is nothing improbable in the idea that, in some cases, in the interchange of filaments between the ganglionic and cerebro-spinal nerves, more motiferous filaments than ordinary have reached organs commonly involuntary, and thus subjected them to the stimulus of volition. That they at all times receive some such filaments is probable from what we know is the case with respect to the sensiferous nerves; almost every organ of the body, however insensible to common impressions, being sensible under extraordinary excitement, such as that produced by inflammation or spasm.

by volition, and such affections, therefore, are all more or less easily and perfectly counterfeited; or these actions may be to a certain extent controlled, and the tendency to such affections may, therefore, be in general counteracted when circumstances forbid their indulgence (a). In like manner the action of the numerous muscles by which the alimentary matters are taken, chewed, or transmitted to the pharynx, by which the stools and urine are excreted, and by which copulation is performed, although commonly either sympathetic or instinctive, may be excited, or, to a certain degree, coerced by volition; and it is thus that we are enabled to modify these actions according to circumstances, as well as to choose a proper time and place for their performance. Again, the dilatation of the nostrils, the downward and outward motion of the eye-ball, winking, frowning, and the innumerable changes in the expression of the features, the voice, the attitudes, and the gestures, commonly resulting from various kinds of emotion, are all more or less easily and accurately effected or regulated by volition also; and it is, as before observed, in the delicacy of his perception of those effects of passion, and the skill with which he imitates them, taking care, at the same time, to control the expression of any real emotion by which he may be actuated, that the whole art of the player consists (b).

(a) Some of these processes are with great difficulty, and in general very imperfectly feigned—for example, sneezing; and there are not many good artificial sobbers or laughers. On the other hand, some require a very strong effort to restrain them—for example, hiccoughing; and every school-boy has felt the inconvenience, in the form of a good caning, of the difficulty with which a strong tendency to laughter is kept in wholesome subjection.

(b) It will hence be easily understood why a man of genius is generally a bad dissembler, and a man of talent a good one; in the former, the instinctive impulses preponderating, in the latter, the rational. The same preponderance of the feelings over the judgment distinguishes a partially imbecile or insane person; and hence the privilege generally conceded to such persons of speaking and acting as they list.

REMARKS

ON THE

TRIAL OF ROBERT REID,

FOR THE MURDER OF HIS WIFE,

BEFORE THE HIGH COURT OF JUSTICIARY,
AT EDINBURGH,

On the 29th of June, 1835.

By JOHN FLETCHER, M. D. F.R.C.S.E.

LECTURER ON PHYSIOLOGY, AND ON
MEDICAL JURISPRUDENCE.

(Continued from page 71.)

2nd. The next consideration is the discoloration of the skin of the back of the neck and spine, which was presumed to indicate *ecchymosis*, the result of an injury inflicted during life. And in the first place respecting the *period* at which this discoloration first displayed itself. It certainly was not seen at half past two o'clock on the Saturday, the day of the supposed murder—by which time it has been presumed that the rigidity of death had supervened—by either Mrs. Tod, Mrs. Chisholm, Mrs. Ness or Mrs. Thomson, although Mrs. Ness and Mrs. Thomson examined the body carefully, and must have seen, as Mrs. Ness avers, such discoloration had there been any; nor was it observed at eight o'clock in the evening of the same day by either Mrs. Fife, Mrs. Thomson or any body else who assisted at the examination of the body at this time. Mrs. Fife

and Mrs. Thomson were again present at the subsequent examination at eleven o'clock the same evening, with Bailie Walker and Mr. Williams the surgeon*, but still neither saw any discoloration, nor heard any spoken of; as was also James Fife, who saw "no spot or blemish," and in answer to whom Mr. Williams said that he found no marks of violence upon the body, and that *the woman had died a natural death!* This declaration was made *fourteen hours* after the supposed injury. The first word we hear of discoloration is from Bailie Walker, who says that *he* observed, on this occasion, "some black sort of marks about the neck, the principal being below the right ear." He afterwards says that "the principal marks were on the back of the neck and down the spine;" but on his cross-examination by Mr. James Anderson, the talented counsel for the prisoner, admits that they did not look down the back on Satur-

* Concerning Mr. Williams—the first of the only two *medical* men who saw the body, or any part of the body in this case—who swore in open court that he had a diploma from the College of Surgeons of London, and on whose report the opinion of the principal medical witnesses for the crown almost entirely hinged, I shall have to say more anon. In the mean time I have only to remark that he was utterly unqualified and unauthorized to give any medical evidence whatever.

day night—that the body was not turned over at that time—and that these latter marks were not noticed till the next examination, on Sunday at four o'clock, or *thirty-one hours* after this alleged injury. Now from what cause must we in candour conceive that marks now for the first time manifesting themselves arose—whether were they indicative of *ecchymosis*, a vital process the result of a blow, or of *livor*, a dead process the result of the *post mortem* porosity of the vessels? Dr. Forbes, one of the crown witnesses, remarks that “if the woman had been killed at nine o'clock on Saturday morning, he would have expected the *livor* from the blow” (*i. e. ecchymosis*) “to appear by two; and if it did not show itself by eight in the evening, it would never show itself at all.” And to the same effect says Professor Trail, another witness on the same side, that “*ecchymosis* cannot take place after death; *livor* may;” and again, “if *ecchymosis* were not visible by the time rigidity commenced, it would never be visible by colour afterwards.” But the discoloration in question was not visible by eight in the evening of Saturday, nor for many hours afterwards, and certainly not by the time rigidity has been presumed to have commenced; so that, by the showing of their own colleagues, a discoloration which the crown party in general has presumed to indicate *ecchymosis* did in fact indicate only *livor*. Dr. Forbes, we find, makes no difference between the two, and instances a black eye as an example of *livor*—but the unbecoming manner in which he attempted to silence counsel, obviously much better instructed in this matter than himself, is unworthy of any notice. It was deposed likewise by Drs. Mackintosh and Robertson and Professor Lizars, that a true *ecchymosis* from a blow would in all probability have occurred, according to the first, almost immediately, according to the second, within the first two hours, and, according to the last, within from four to six hours after the reception of such blow. Professor Christison, on the other hand, seems to regard the time of the appearance of *ecchymosis* after an injury as much less certain than that of the manifestation of *livor* after death, the extreme limits of which he represents as five or six hours; and observes that “if no *livor* were seen at eight o'clock on Saturday evening, there must have been some extraordinary error in the facts.” There were, Heaven knows, many “extraordinary errors in the facts,” and such as one would suppose might have invalidated, in the mind of every unprejudiced medical witness, any conclusion whatever from them; and in particular the conclusion that this poor woman was murdered at nine o'clock, rather than that she died a natural death at a little before two. But Professor Christison's opinion, far from weakening, is a corroboration of the inference

to be drawn from that of the other medical witnesses, that the discoloration in this instance did not originate in *ecchymosis*, but in *livor*; for, if it follow from their statements that it could not have been *ecchymosis* from its late appearance, it is an equally fair corollary from his, that the marks which first displayed themselves resulted from that cause which is most uniform in its operation, and was therefore *livor*. Nothing was said on the trial respecting the more or less determinate margin of the discoloration, or of the precise situation of the blood, as merely loosely diffused through the substance of the skin, and that perhaps only a very thin stratum near its surface, or compactly incorporated with the substance both of the skin and of the subjacent cellular tissue—the generally received grounds of distinction between *livor* and *ecchymosis*—the incompetency of those who witnessed the marks in question having rendered quite vain the hope of illustrating the real nature of the discoloration by any observations like these. And with respect to that green or yellow colour which, in the living body, after a time characterizes the latter, this criterion of judgment would of course in the dead body be wanting. There can nevertheless be little rational doubt that the discoloration now under consideration resulted from the dead process of *livor*, and not from the living process of *ecchymosis*. The death of the woman, however occasioned, had been sudden, in which case the blood commonly remains for a long time fluid. The corpse was placed on the back about half-past two o'clock on Saturday, and the posture had undergone only temporary changes till eleven, when “a black sort of mark” is said to have been perceived under the right ear; and this posture remained again unchanged till four o'clock the next day, when similar marks were observed on the back of the neck and down the spine: all which marks are described by Dr. Forbes, who saw them the day after, as presenting “a livid appearance, but nothing more than what is usual in dead bodies which lie twenty-four hours on the back.” And that this black sort of mark should show itself first under the right ear may perhaps be accounted for either from the sore on the head, under which we find, from the evidence of Mrs. Wilson, the deceased had laboured, and which, as observed by Dr. Robertson, had probably rendered this part more vascular than the rest; or from the curvature of the spine towards the right, which Professor Lizars reasonably enough supposes might have produced an inclination of this side of the head downwards, when the body was placed on the back. It may be remarked further that, upon the presumption that the supposed blow was inflicted while the woman was in bed, as paralytic patients usually lie on the sound side, which in this woman was

the right, and seldom or never on the face, the right side of the head and the back of the neck and spine are the very last parts upon which such a blow was likely to fall; while, on the other hand, these parts being after death undermost, and comparatively free from the pressure of the surface on which the corpse lay, and which, contrary to the statement of Dr. Forbes, is known to every well-informed medical man to obviate, instead of promoting the occurrence of *livor*, are precisely those in which we should have expected an accumulation of blood from this cause. So much for the *period* at which this discoloration first manifested itself: again, how far does the *extent* of this discoloration correspond with the idea of its having resulted from a blow inflicted during life, with the blunt extremity of an axe, upon the upper part of the spine? Baillie Walker says that it extended three or four inches down the back; and Mr. Williams, that it reached to the sixth vertebra; but whether it were the sixth cervical, the sixth dorsal, or the sixth (!) lumbar vertebra, as he was ingeniously asked by the counsel for the prisoner, he was quite unprepared to determine. And indeed such depth of information could hardly be expected from one who was totally ignorant of the number of vertebræ in the spinal column, who described, in writing, the first *series* of vertebræ as formed by the atlas, and the second by the "*tentata*," (*dentata*) and who represented the "*outward jugler*" (external jugular) vein, first as carrying the blood from the "*hart*" (heart) to the brain, and afterwards, by way of an amendment, as carrying it from the brain to the "*hart*;" and yet it was upon the presumption of the accuracy of the statements of this man that the very essence of the *corpus delicti* principally, and almost entirely rested*! We find from the

evidence of John Arnot that Williams cut "from the crown of the head all the way down the back;" and from that of Baillie Walker, that he cut "as far as he saw blackness." Hence it results that the discoloration really extended all the way down the back, as well as "to the top of each shoulder;" for such was the direction and extent of a transverse incision which Williams made on this occasion, "at least eight inches," as Dr. Forbes says, "below the seat of the dislocation," which was afterwards discovered. And with respect to the longitudinal incision, the evidence of Dr. Forbes bears that this extended "from the occiput to the second or third lumbar vertebra;" so that, to wave the slight discrepancy between these two *medical* gentlemen of some fifteen or sixteen vertebræ—for Williams' sixth was afterwards explained to mean the sixth from the head—we seem justified in supposing that it reached from one shoulder to the other, and from the head to the loins. Now is a discoloration of this extent what we should have expected from any blow, and in particular from such a blow, and in such a situation as is above supposed? Professor Christison indeed says that "a blow might have produced the livid appearance described." Not, I am afraid, without the admission of another "extraordinary error" or two in the facts, a too frequent repetition of which would have ended probably in an extraordinary error of a very melancholy description.

3rd. But perhaps the least equivocal characteristic of *ecchymosis*, as distinguished

he called it, "the Body" of Surgeons of London—that he *swore what was false*, in first stating that he had such a diploma, and again in stating that he had not been cited (which he was three several times) to produce it—and that Reid was in danger of being sacrificed on the representations of a man who was not only unauthorized to give any evidence at all in this case, but who was obviously no more competent to describe the appearances presented on the dissection of a dead body than a street porter? How any respectable medical witness could build and maintain an opinion upon the statements of a man the grossness of whose ignorance was so apparent is inexplicable; but it is highly gratifying, at the same time, to find that the *exposé* of want of knowledge on this occasion cannot affect the character of the profession in general. There are few practitioners, even in the most obscure towns of Scotland, who are not at present distinguished by an extent and precision of information which not many years ago were the attributes only of a chosen few, even in cities; and there is hardly a first-year student now in Edinburgh, who could have disgraced himself by such a display as was made in this instance.

* It was suggested by the court that an accident which Surgeon Williams had *so very inopportunistically* met with the day before that on which the trial was first expected to come on (16th of March), and which had entailed upon him a loss *so very inconvenient* to a witness in a court of justice—that of speech, might have so far impaired his memory also, that he was inadequate to answer these *very searching* questions, and the witness deposed accordingly that his memory *was* very much impaired: but, with submission, if his memory were too treacherous to enable him to answer questions which the veriest tyro in medicine would have felt humiliated at being called upon to solve, it was certainly too treacherous to be trusted—and that without a shadow of notes taken at the time of the investigation—in an affair which involved the life of a fellow creature. But what will the public think when told that Williams is no surgeon at all—that he never had a diploma from the Royal College, or, as

from *livor*, is the presence in the discoloured part of coagulated blood; and it appears from the evidence of Williams, that "a quantity of coagulated blood" issued from the mark below the right ear, upon his dissecting away the skin from the part—a conclusive proof, in the minds of Professors Christison and Traill, that this mark was the result of an injury inflicted during life. But admitting that it would have been so had the fact been established, what evidence have we that the blood which issued from this part was really coagulated, except the *ipse dixit* of a person, who, from the display which he made with respect to the solid parts, may be fairly presumed to be quite incompetent to make any nice distinctions in this respect? And indeed there is strong presumptive evidence that the blood found in this part was in fact in a liquid state. Bailie Walker expressly says that, at this time, "Williams did not cut under the right ear"—"did not cut nearer to the right ear than the centre of the back," and Dr. Forbes equally explicitly states that "the skin was not cut away at all," so that the blood in this part could find an exit only indirectly by some one or other of the wounds in the neighbouring parts; and yet this blood is described, both by Bailie Walker and by James Fife, as *flowing* from this spot below the right ear, leaving the part which had previously been "as black as their hat" without the least appearance of discoloration. Now can this be true of really coagulated blood, closely incorporated with the substance of the cellular tissue and skin, and that at a distance from the part in which the incision was made, or does it imply that the blood was still in a liquid state, and only loosely diffused through the substance of the latter? It is obvious to common sense that whatever blood came thus from the discoloured parts could not have been coagulated. "It was *thick*," says Bailie Walker, "but it still *flowed*;" and Professor Christison admits, in his evidence, that the term "thick," is often applied by people in general to the blood as it flows from a vein in the ordinary operation of blood-letting from the arm, when it is still perfectly liquid. We have no right then to assume, as Professor Traill thought proper to do, that when Bailie Walker called the blood thick, he intended to express that it was coagulated; and as to what Williams meant by the use of the latter term, the presumption is that he had no distinct meaning at all. Further, if the blood had been really coagulated in this or any other part where the discoloration was seated, it could not, as remarked by Professor Lizars, have all escaped, but must have left traces which would have been visible the next day, when Dr. Forbes distinctly says he found nothing unusual. It is no doubt highly probable that a portion of partially coagulated blood did in fact issue

from some of the subsequent incisions made during the carving to which the body was on this occasion subjected, such blood oozing directly from certain large vessels which were inadvertently divided, and constituting a great part of the "half pound" or "half tumbler" described by the witnesses as coming from the discoloured parts; but this has nothing whatever to do with the presumed *ecchymosis* in question*.

4th. And this brings us to the next subject of inquiry, the alleged rupture, by a blow, of the right external jugular vein, whence Williams chose to imagine that the alleged coagulated blood *constituting the ecchymosis* below the right ear, had proceeded. But, to omit the inaccuracy of calling that an *ecchymosis*, which, had it occurred, would have been, not an *ecchymosis*, in the proper acceptance of the term, but a *thrombus*, and the total inapplicability of this doctrine to explain the extensive discoloration down the back—it is in the highest degree unlikely that there was any such rupture of the right external jugular vein at all. This may be fairly inferred, partly from the extreme rarity, as stated by Dr. Robertson, of this accident from a blow of any kind, and the excessive improbability of its resulting from such a blow as should at the same time fracture the vertebra dentata, partly from the very tardy appearance of the discoloration in question, and partly from there not having been, at any time, the least appearance of a tumour about the part, as distinctly deposed by the witnesses Mrs. Chisholm, Mrs. Ness, Mrs. Fife, Mrs. Thomson and Williams himself. The external jugular vein proceeds, as every body knows, from the parts about the face down the sides of the neck, immediately under the skin, and is altogether out of the way of the upper part of the nape of the neck, in the depths of which is situated the vertebra dentata; and as to a rupture of this vessel having deposited "as much as half a pound of blood," or "as much as would fill a half tumbler," below the right ear, without producing any tumour, it is perfectly incredible. If blood came from the large blood-vessels at all, it was in all probability in consequence of Williams having wounded them by incisions, which are designated by his coadjutor "as any thing but what he should have expected from a surgeon," and such blood was in all likelihood partially coagulated. Nor can it be urged by those who ascribe the peculiar posture in which the body of Mrs. Reid was found to the rigidity of the muscles, as any

* "The effusion of fluid blood from vessels in the neighbourhood of which it is coagulated must have occurred *in the dead body*." (Dr. Christison's Cases and Observations in the Edinb. Med. and Surg. Journ. vol. xxxi.)

objection to this opinion, that after a sudden death from any cause, the blood in the large blood-vessels is rarely found coagulated. In such cases the muscles rarely become rigid, the same causes operating, at least frequently, in obviating both these phenomena*; so that the witnesses for the crown, in denying that coagulated blood could have been discharged as a consequence of such incisions, appear to be on the horns of a dilemma, since, if they deny that the blood in the large blood-vessels would in this case be coagulated, they cannot very consistently maintain their position with respect to the assumed rigidity of the muscles—if they cling to this assumption, they must at least admit the probability that the large blood-vessels, if cut, would exude a portion of at least partially coagulated blood. Williams, indeed, says that his scalpel did not approach the right external jugular vein, and that he only “dissected away the skin from it;” but, to say nothing of the impossibility of doing this without “his dissecting knife coming near it,” it is stated by Dr. Forbes that one incision made by Williams in the neck was “from one jugular vein to the other—as deep as it would go—close to the bone—as far round as the angle of the jaw.” I can no more understand this description of the incision than could Professor Traill, nor perhaps did Dr. Forbes himself; but it is evident that it was a pretty deep and extensive one, since we shall in future find that it was by putting his hand into this gash that Dr. Forbes alleged that he discovered the fracture and luxation of the vertebra dentata. By this incision several large blood-vessels, arteries as well as veins, must of necessity have been divided, and where is the improbability that some partially coagulated blood would issue from these, or that such blood would be confounded by any one who could make such an incision with the still liquid blood which flowed from the discoloured parts, and constituted the *livor* mistaken for *ecchymosis*? Can we believe that such a one was competent to distinguish between the effects of his own reckless operations, and a rupture of a vein produced by violence inflicted during life? In this way it is easy to understand why the spot below the ear was the only one of the discoloured parts which appeared to exude coagulated blood. But it appears that it was not only an atlantic of *ecchymosis*, a rupture of the right external jugular vein, “opposite (!) the vertebra dentata,” (I will not offend my readers by again copying this person's orthography) and, as we shall presently find, a fracture and luxation of this vertebra dentata, which resulted from the imaginary blow in

question, but also some tremendous mischief or other on the *left* side of the neck, since Williams found here likewise, as he deliberately stated in writing, “behind the left ear, on dissecting away the skin, the resemblance of a blow or concussion!” What any man could possibly mean by “the *resemblance* of a *blow*,” and still more by “the *resemblance* of a *concussion*,” even supposing, as we are perhaps in charity bound to do, that he intended to say *contusion*—as he intended perhaps to say thickened, when in speaking of the blood, he called it coagulated—I am at a loss to conceive; and how any well-informed medical witness could sit by to hear such arrant nonsense, and still hold to any opinion founded upon the evidence of the man who could utter it, is still more unaccountable.

(To be concluded in our next.)

SELECT LECTURES,

FROM

M. BROUSSAIS'

Course of General Pathology and Therapeutics;
translated and revised

By JAMES MANBY GULLY, M.D.

LECTURE X.

Inflammations of the Pneumo-gastric Mucous Membranes, continued.—Otitis—Coryza.

OTITIS may present itself in any of the three divisions of the auditory apparatus: in the external meatus, in the cavity of the tympanum, and in the internal ear. It is of much less importance in the former, which is only a duplication of the skin, than in the two others. The cavity of the tympanum includes a sanguineous, secretory mucous membrane, which acts the part of periosteum, as also muscles, a chain of small bones, nerves, vessels, and a very dense cellular tissue for the connecting of the various parts. Inflammation may be seated in this mucous membrane, and be communicated to the lining membrane of the mastoidean cells in the adult, to the Eustachian tube, and to another small membrane which closes the entrance to the labyrinth. It may likewise be developed in the labyrinth, where there is a cellulo-serous membrane of extreme tenuity, the delicate expansion of the acoustic nerve, the humour in which it floats, and extremely minute nerves and vessels.

The causes of this inflammation (which may be either acute or chronic), are those common to all inflammations, as well as those dependent on the function of the organ, such as inordinate noises, a violent explosion as of a battery of artillery, to those not accustomed to it, or even to those that are, if the undulations of the air are directed straight to the ear, and the shock is so violent as to cause hæmorrhage—inflammation succeeds upon the latter.

* “The coagulation of the blood appears to happen soon after the stiffening of the muscles begins.” (Dr. Christison, Op. Cit.)

Cold is one of the chief causes of otitis: and calorific rays from a furnace may cause it. The predisposition consists in a state of the mucous membranes that is frequently met with in infancy; hence the phlegmasia in question is more common in that age.

When it is developed in the external auditory canal, there is sometimes no pain at all: there is only a slight tickling, and suppuration ensues. This slight catarrh is seen primarily on the impression of cold, or consecutively, or critically, after internal phlegmasiæ. Still the inflammation may be tolerably severe, may be propagated to external parts, tend internally, and even traverse the membrana tympani. Its characters are pains of the part, more or less redness, and tumefaction, an anormal ceruminous secretion and disturbance of the sense of hearing.

Inflammation of the middle ear presents much more serious symptoms, and in it otitis is seen in all its fury. The patient experiences acute pains of the ear, that seem to pass into the interior of the cranium. The exaggerated sensibility of the part makes him feel the beating of the small arteries like so many strokes of a hammer. There is no external discharge, unless the membrane of the drum has been previously perforated; but there is sometimes a discharge by the Eustachian tube, which it is difficult to detect, unless we are led to the examination of the part by the pain, and then we find the mouth of the tube, at the back of the throat, red, and a purulent fluid proceeding from it. The peculiarity of the inflammation is the violence of the pain, and the activity of the sympathies, of which there are none in the case of the external canal. Pains of the head, sleeplessness, fever, painful throbbings and shootings, and an incessant buzzing sound are present; all the sensations are exalted; the eye of the diseased side is frequently injected, or the whole side of the face is sometimes reddened. When the inflammation extends to the mastoid cells, percussion over them is painful, and the corresponding skin is injected and more sensitive.

That inflammation, which takes place in the innermost portion of the auditory organ, in the cochlea and demi-circular canals, is so obscure as most frequently to defy a diagnosis; and as there are but few blood-vessels in the part, it cannot possess a very decided inflammatory character. It is ordinarily confounded with headach, and is accompanied with divers noises, jingling, running and falling water, &c.—in short, there is at once incessant noise and headach.

As to the progress, propagation, and termination of otitis, the external inflammation is apt to end in suppuration in a certain number of days, but occasionally it may remain in a chronic state, in which case the ceruminous matter not returning to its natural condition, it may concrete at the bottom

of the canal, and produce deafness. This circumstance, which is frequently not suspected, has given rise to many marvellous cures, when those who paid more attention to the matter than their predecessors in the case, extracted the hardened wax from the opilated passage. Such an occurrence is most commonly remarked in individuals of a lymphatic or scrofulous constitution, but is also possible in others of sound habit of body. External otitis, if very acute and not arrested, may pass through the membrane of the drum and reach the middle ear, in which case pulsations, pains of the head, and sleeplessness, are experienced. Inflammation of the middle ear may terminate in resolution, though it is rare for it to do so. It is always prudent to strive to suppress it, lest it reach the internal ear and annihilate the sense; this more especially happens when the disease passes into the chronic state. When exceedingly acute, perforation of the membrana tympani from within outwards may occur; the converse, that is, perforation from the exterior inwards obtains in other cases. The inflammation may likewise be propagated to the Eustachian tube and end in suppuration: the pus is then sometimes discharged by that route, but more frequently it is closed. If the membrane of the drum is perforated, a great quantity of pus suddenly flows by the external canal, provided the Eustachian tube is open, a fact which we ascertain by stopping the other openings during the act of expiration. Sometimes the inflammation takes another direction, and penetrates the mastoid cells, particularly in adults, is communicated to the external table of the bone and the superimposed tissues, producing a phlegmon behind the ear, which is a means of resolution. Such a happy issue is, however, far from being frequent; more commonly the inflammation remains predominant or concentrated in these cells, and produces suppuration in them, which finds exit behind the ear, after having destroyed the bony parts; so that after the opening a caries is left.

Propagation to the brain is possible when the inflammation has commenced by the middle ear, but less so when its starting point is the labyrinth. But in whichever it has commenced, we may suspect the propagation when there is extreme pain of head, with violent pulsations, and we may be certain of it when we remark hemiplegia of the opposite side. Instead of hemiplegia we sometimes see a crushing apoplexy in persons that have long suffered from otitis. On inspection we find an hæmorrhage or abscess occupying the middle lobe.

These different progresses suppose that the acute stage has maintained a certain degree of activity; but it may degenerate into the chronic, and then a discharge by the external ear takes place, accompanied sometimes by the issue of the small bones and portions of carious bones, or else complete deafness en-

sues without any external appearances. I have had the opportunity of examining a body in which the drums of both ears were found broken down by suppuration, the small bones gone, and in their place pus, and small masses of tubercular matter: all which had been accompanied, in life, with the most complete deafness. I make no mention of the propagation of the irritation to the base of the skull and the face, by the nervous communications of the facial nerve with the organ of hearing, a propagation whence a convulsive and neuralgic state of the face may result.

In tracing the progress of otitis, I have described the post mortem appearances to you: I will, however, add some further details. If the disease has been altogether acute, we find redness, pus, a detritus of parts and caries; if it has been at a lower degree of intensity, or has lapsed into subinflammation, a concrete and plastic matter is found incrusting the parts and rendering them immovable. Very many cases of deafness originate in such a mechanism, in early infancy, in subjects of a scrofulous constitution. Sometimes a cheesy or tubercular matter is found, resembling that mentioned in the case alluded to above. As regards the alterations of the brain, they are only accidental, and the result of the propagation: this is not the place to mention them.

You may see on what the prognosis is to be founded. A simple otorrhœa of the external canal is a small affair, though at the same time we must not treat it too lightly, for it is liable to relapses that may ultimately induce deafness. Some individuals are more particularly exposed to it than others, and among them, such as are the subjects of dactyria, ophthalmia, tumefied glands, and in fact of all peripatetic inflammations that may finally fix on the ear. When so fixed, they ever produce the same phenomena and are variously intense, inflammatory, or subinflammatory. In their greatest violence they may bring on the disorders of the middle ear already spoken of, and in the chronic state, when the head has at the same time been affected with apoplexy and hemiplegia. The least we have to fear is deafness—a sufficient reason for not allowing otitis to go on.

This disease, otitis, is observed to be more frequent in certain years than in others, and is epidemic. This afforded me the opportunity of very frequently treating it in military hospitals, where I ascertained that it ordinarily arises from cold. Looking on it as an inflammation I applied antiphlogistics; but you should learn that ten or a dozen leeches are of no use when it is deep seated. We should bleed from the arm to relieve the head when it is gorged, and then place forty or fifty leeches around the ear. Where there is merely otitis, we dispense with the bleeding and trust to the leeching. In this manner I have cured hundreds, and it is un-

doubtedly the surest mode of avoiding the consequences of slow resolve, and those of propagation, caries, cerebral inflammation, &c. Should it be too late to obtain full success from this method, still we must employ it in a modified way. Instead of a great number of leeches at once, fewer may be used and repeated daily or less frequently according to the degree of inflammation and redness observed at the bottom of the ear. This plan succeeded in a young person who had been deaf for eighteen months, with tinnitus. She had been purged until the digestive canal began to be irritated. I passed her to an aurist, who recommended her to apply four leeches every other day to the ear: the success was at first doubtful, but ultimately complete; shewing the utility of antiphlogistic treatment even in chronic disorders. According to circumstances, you may add revulsives, blisters, setons, and moxas. If you like you may deluge the digestive canal with mucus by means of purgatives; but remember that they may generate disease in the organs on which they act, and should therefore be used discreetly. The surest way is always to address yourself directly to the inflammation itself, whenever that is practicable, and above all to nip it in its commencement whenever it is situated in deep-seated organs—a precept than which I can give you no better, and one that *will* finally and necessarily prevail, strong as opposing prejudices may be. Every one, however, does not apply to others what he uses in his own case. Many physicians who go murdering the physiological doctrine in the persons of their patients, apply it very accurately to themselves when they are taken ill. Several such cases I know of, and of these some are of the "crack" race (*des célébrités*). When seized with sickness, they send for another célébrité as a matter of form, but take good care to have some little physiological physician in the way, and he it is whose advice they actually follow. We pass to the inflammation of the olfactory apparatus.

Coryza.—The cause of this inflammation is more particularly found in the action of cold; the exertion of the organ of smell rarely induces it, but such an event may take place; indeed it happened to myself in my youth, at the time I was studying botany: having a very delicate sense of odours, I smelled and tasted the plants, for the better recognition of their properties, and the habit got me several coryzas. Acrid vapours and irritating gases in the atmosphere may also produce the disease. But its most ordinary cause, as has been said, is cold, especially of the head and feet, particularly moist cold, acting by the medium of the air and water; and if it so acts during the night the effects are much more severe. Dry cold does not so readily cause the inflammation in question. The predisposition consists in a tendency to affections of the mucous membranes and a congested state of the head. Youth, a lym-

phatic constitution, and narrow nostrils, favour its development.

Coryza is known by an itching, sneezing, sense of fullness, some bleeding of the nose at intervals, during which the sense of plenitude is done away with, to be however reproduced; a watery and then a mucous secretion is remarked. The mucosities become acrid and burning, inflame and corrode the *alæ nasi*, and even the lips; at a certain point there is heaviness of head and fullness of the entire face.

Propagation may take place into the frontal and maxillary sinuses, to the ethmoidal cells, to the head and the eyes; but it is most commonly directed towards the larynx and bronchi, the coryza being only the effect of a developed irritation in a vast number of mucous follicles at once, constituting a catarrhal state which tends to travel along the course of continuous membranes. Those cases in which it is only the prelude of a cold, or where it ceases in two or three days, must be distinguished from those in which it is inflammatory and obstinate, and where it threatens to cause a purulent collection in the maxillary and frontal sinuses, as well as from those cases in which it is excessively aggravated, accompanied with violent headaches, stupor, and complete loss of smell; in such instances it may reach the brain. Examples of such a propagation are more rare in coryza than in otitis. I have seen several of them, however. Why does it not occur more frequently? Is not any thing possible in inflammation? and can it not take all kinds of directions? Here then is a lesson for us to be astonished at nothing.

The sympathetic or disseminative phenomena are ordinarily slight, there being only lassitude, tremors of the limbs, and little or no fever; to give the latter a decided form there must be inflammation of some organ.

Common coryza, induced by cold, and which is not maintained in the upper part of the mucous membrane by any local predisposition or a long standing point of irritation, ends in three or four days and is replaced by a cold. But if it is fixed and obstinate, with sense of fullness, prostration, &c., the mucosities become thick and fetid; ulcerations of the mucous membrane covering the turbinated bones sometimes appear, spread, and penetrate the bones, producing polypi, caries, and ozena; or else pus accumulates in the maxillary sinus, the cheeks swell, become red, an abscess forms, and requires a surgical operation to give exit to the matter: this should be done in good time, to prevent the necrosis of the bone.

Coryza is sometimes exceedingly obstinate when it is accompanied with incessant bleeding of the nose and continued pain of the head after cerebral congestion. I know a person who had one every time he became cold, but who speedily got rid of it. He was once attacked when in a state of plethora and headach, in consequence of having

neglected to be bled; this time the coryza did not yield spontaneously, because it was kept up by a severe engorgement, while at the same time that there existed an irritation and congestion of the brain, there was a similar irritation and congestion of the mucous membrane; vigorous antiphlogistic treatment became necessary in this case. Simultaneous congestion therefore of the face, gums, eyes, &c. is a cause of prolonged and obstinate coryza; but in this state of things the coryza would tend less to supuration, and would rather be a precursor of apoplexy if the afflux of blood upwards is considerable.

Dissections only give us information on the complaint when death comes accidentally, for no one dies of coryza, unless there be ozena and propagation to the brain. The mucous membrane is then seen to be red, ulcerated, thickened, degenerated: the bones of the nose and sometimes those of the face carious: the same at the base of the brain; the inflammation propagated to the anterior lobe of the brain, with all the consequences it entails upon that part.

As regards the prognosis, it may be said that purely mucous and catarrhal coryza is a slight disorder; it is well, however, to obviate it as much as possible. The inflammation that remains fixed in the nasal mucous membrane merits the utmost attention, especially if ulcerations and a tendency to ozena appears. This case is more serious than a simple congestive disposition of the brain; for notwithstanding the latter, the disease may still be readily overcome, unless indeed there be some previous alteration of the brain. Deep-seated coryza that degenerates into ozena and induces caries, is therefore a serious matter.

The treatment should be commensurate with the degree of irritation, of propagation, individual predisposition, and cause. Have we to treat a coryza brought on by cold, it is soon done; keep warm, re-establish the cutaneous transpiration, prevent propagation to the lungs, that is all. Does the coryza remain fixed in the nasal fossæ, and is there redness and tenderness of the face, it must be treated as a local inflammatory affection, by leeches to the apertures of the nostrils, by demulcent baths, mustard baths, low diet, and slightly sudorific demulcent drinks. If there is a cerebral congestion along with it, these means should be preceded by bleeding in the arm or foot. Should this pre-existing congestion have been shared, previous to the coryza, by the pneumogastric mucous surface, we are right to persevere in local bleedings, which should be repeated with a pertinacity equal to that of the disease; in this manner, by this obstinacy in my plan, I have vanquished many severe coryzas.

We then prescribe a diet in accordance with the state of the patient. When the excreted matter happens to be fetid, and there is a tendency to ozena, local bleedings may still

be employed; but the nasal fossæ should be carefully excluded from the air, and the openings to them accurately stopped with cotton wool. This simple precaution, founded on attentive observation of the morbid phenomena, makes cases curable that would not be so without it; by this means incipient, and even advanced ozena, may be cured. But if the disease is deep-seated and inveterate, with threatening or commencing caries, and especially if there is at the same time suppression of some cutaneous excretion, we cannot do better than to have recourse to some exutory applied on chosen points, and, in the last named case, over that occupied by the irritation. If abscesses form, they are to be opened, and we should strive to undermine the inflammation that surrounds them, without which we are not likely to succeed.

In the course of our descriptions of the inflammations of the apertures of the mucous membranes, wherein or whereon the external senses exist, we have had occasion to remark several traits which they have in common. In general they are accompanied with mucous secretions: when there is great activity they influence the viscera, and are influenced by them; their proximity to the brain renders propagation thitherward easy; these are facts which you ought not to pass lightly over.

We now proceed to speak of the inflammations of the mouth. They sometimes extend to such a depth that they are no longer visible in their whole extent; but we must now begin to study inflammation in organs which the eye can no longer reach. Hitherto we have closely staid by our analytical method, which consists in the studying morbid phenomena in every point where they impinge on the senses, where their immediate characters and influences are readily detected, and where deduction is less difficult. Proceeding thus, we have constantly remarked, that the disorder of the internal functions bears a ratio with the local inflammation: we have always seen, from the natural progress of the latter, or the impulses it receives, the visceral irritation augment or diminish according as the local inflammation augments or diminishes—in short we have always beheld it march in concert with it, in the character of an effect, except when, as I said before, a previous inflammatory condition of the viscera has paved the way to the external phlegmasia.

HOSPITALS, DISPENSARIES, AND WORK- HOUSES.

To the Editor of the *London Medical and Surgical Journal*.

SIR—I have lived in the metropolis for upwards of forty years, and the whole of my observation, during that extended period, confirms the representations of Amicus Industriæ.

The receiving-rooms of hospitals and dispensaries, and particularly the former, are marked by great indecorum of manner and language on the side of the subordinates: indeed the whole system, in all its features, is saturated with grossness and imperfections, because sordid hypocrisy and deception reign thereat; such institutions being much more useful to the aristocracy and the wealthy than the poor; and this most disgraceful perversion of charity will only cease when disease and misery receive protection on these sacred and irresistible appeals, and not because the afflicted are the dependants of this lord or that lady. Until this shall take place, our charities are our disgrace, not our ornament; and we shall continue to be regarded in this department of human misery, by all humane and enlightened foreigners, as strongly tainted with barbarism—as a nation of hypocritical, Christian Jews—acknowledging Christianity, but practising none of its sacred principles; a nation, as observed, professing Christianity, but enacting Shylock with singular fidelity. In further proof of want of Christian feeling, let it be remarked, that the inexperienced medical man is oftener appointed to those hospitals and dispensaries than the experienced, so that these arrangements are more allied to destruction than benevolence and charity.

Amicus Industriæ observes, that the medicines at these institutions are often bad, and carelessly prepared, and to the truth of which I can bear testimony; and will add, that a hungry dog, of cleanly habits by nature and education, would not touch a joint, even under this strong impulse, if found in contact with the dirty powders, pills, and bottles emanating from the foul sources adverted to.

Kings, their ministers, and secretaries, admirals and generals, bishops, the officers of the Excise and Customs, of the Vaccine Board, of the British Museum, all delight in being refreshed by the approaches of the golden calf—I beg pardon, I mean the golden shower of prolific power, and far surpassing the southern breeze. But excessive virtue always verges on folly, and the ridiculous is to be alone found in the medical officers of dispensaries, who receive no remuneration for their services thereat, while themselves and their families are not unfrequently under great difficulties.

I am, Sir,

Your most obedient,

Humble servant,

A FRIEND TO REMUNERATION FOR
MEDICAL SERVICES.

London, August 7th, 1835.

[There is nothing more unreasonable and unjust than expecting the services of medical practitioners, at hospitals and dispensaries, gratuitously. This custom began in former ages, when the profession very

humanely afforded their services to the poor without fee or reward. In those days there were no poor laws, nor poor law commissioners, to compel parishes to support their poor. But now we have both in luxuriance, and the latter are sagely proposing, to needy and inexperienced young professional men, to doctor the poor at a farthing a head. Such is the race of political intellect.

There cannot be a second opinion, but the poor rates of this country are more than sufficient to secure the proposed advantages to those unable to procure subsistence, and also to remedy their diseases. But how are they applied? In the grossest speculation in most cases. Who are the medical officers? Men just let loose from school, who are in general incompetent to prescribe for a dog or cat, but who work cheap. Aye, there's the rub. Would the poor law commissioners employ such practitioners in their own families? The answer is no; but they are good enough for the poor. Now the health of the poor is as valuable as that of the rich, and their diseases as important. It surely is no crime or sin to be poor. There would not be any difficulty in proving, that the medical attendance on parish poor is the worst on the face of the earth. The medical attendants are not in general allowed the price of shoe-leather for their services; and, as to that of a horse or donkey, it is out of the question. Yet the poor law commissioners expect respectable medical practitioners to render their services on such terms. Pshaw—non-sense. They must have no common sense. It is scarcely necessary to observe, that medical practitioners, physicians, and surgeons, contribute as largely to the support of the poor as other citizens. Then, in the name of reason, why should they alone do more for the poor than all other individuals? Why should they give their services at hospitals or dispensaries gratuitously, when the metropolitan hospitals are opulent, and the parishes are bound to supply medical aid to the poor? Why should general practitioners be seriously injured by hospitals and dispensaries? If they act wisely, they can readily abate the evil. Let meetings of the profession be held, for the purpose of placing hospitals and dispensaries on a proper basis. Let such meetings resolve, That none but real objects of charity be admissible to such institutions; and that the medical officers henceforth refuse to act gratuitously, and to admit all improper persons recommended. By this means society, and the faculty, would be really benefitted. *Let meetings of the profession be generally convened as soon as possible, and solid good will result.*—ED.

MEDICAL JURISPRUDENCE—DR. ALEXANDER'S REPLY TO THE MEDICAL GAZETTE. —

To the Editor of the London Medical and Surgical Journal.

SIR—The following are the remarks in the London Medical Gazette, No. 42, on my evidence:—

“Another medical witness was now called, whose evidence was any thing but serviceable to the side on which he appeared, or indeed creditable to the deponent himself. Dr. Alexander, Surgeon, saw Col. Gusvalde in May, 1827, at Macclesfield; he was in bed; never saw him under an attack of epilepsy or under a fit of any kind; yet a certificate was given by witness to this effect, that having examined the patient, he found that he had been labouring under epileptic fits, followed by delirium, in consequence of a fall, and that he would not be able to resume his duties in a less period than six months. This certificate was got up in order to procure leave of absence for the Colonel from the Horse-guards. Counsel for the opposite side naturally laid much stress on the evidence of Dr. Alexander, and admitted, that were it not for the certificate just quoted, the plaintiff's case would have gone triumphantly before the jury.

“Nor can we avoid saying a parting word regarding the predicament in which one of the witnesses placed himself (we mean Dr. Alexander), who was obliged to confess his having given a certificate without the requisite caution, and that he stated circumstances in it of which he had no personal cognizance, the document being at the same time ambiguously worded. The dangerous indiscretion of such a proceeding is but too obvious to require further remark: with the morality of it we will have nothing to do.”

Extract from my Annual Report for 1827.

One of the contusions was very severe, and occurred in an officer at Macclesfield, who was thrown from a footpath into the road (the footpath being raised several feet above the road), and pitched on the back part of his head. This happened on the 7th May, 1827, and on the day following (8th), whilst Captain Wigley* was walking in the street, he suddenly fell down, foamed at the mouth, and remained convulsed for some hours. He was now freely bled and purged, and remained in bed until the 11th, when he got up, conceiving himself recovered. On the 12th he was driven out in his gig, but soon returned, looking and feeling very unwell; yet, not, withstanding, he on the 13th visited one of the stables, where, whilst in the act of stooping, he fell down, and remained many hours convulsed. He was now put to bed again and bled, &c.; but on the 14th and 15th he was seized with noisy delirium. On the morning of the 15th leeches were applied to both temples, cold lotion to the shaved head,

[The following was excluded last week, for want of space.]

* Afterwards Col. Gusvalde.

and afterwards a blister. Towards the morning of the 16th, he became more composed, fell asleep, and awoke calm and sensible. I saw him at three, P.M., of this day (16th), when he still continued calm and sensible, but rather hurried in his manner. Pulse quick and soft; eyes impatient of light; and he still felt pain in the back part of his head, a little behind the left mastoid process, although much less than formerly, and pressure caused a slight increase of pain. As the disease seemed to be subsiding or subdued, I had nothing to advise but a repetition of the same means that had been employed, if a recurrence of symptoms required, and that in the meantime his bowels should be acted on, iced water applied to the head, and quietude, low diet, and a dark room, should be strictly enjoined.

The following certificate was granted on the fifth day after my visit to Macclesfield:—

"I hereby certify having carefully examined Captain Wigley, and find that he has been labouring under epileptic fits, followed by delirium, in consequence of a fall on the head; and am of opinion that he will not be able to resume his duty with safety in a less period than three months.

"M. ALEXANDER,

"Staff-surgeon, late of the 6th Dragoons.
"Nottingham, 21st May, 1827."

Sir—I regret that circumstances should have occurred to prevent me from replying earlier to the remarks contained in No. 42 of the London Medical Gazette, touching my evidence in the late trial of Chattock v. Shawe. The false statements and omissions in the article on Policies of Life Assurance, renders it unworthy of a place in any of the farthing trash that daily issues from the press.

Allow me to state that I shall take up no more of your space than is necessary towards the refutation of the base and (I hope) unmerited remarks of your charitable contributor.

The learned judge, in addressing the jury, stated that some part of the evidence had been withheld—an important fact, of which, no doubt, your correspondent was fully aware. Lord Abinger also stated that it was of no moment whether the fits were epileptic or not; for if the jury were satisfied in their own minds that Captain Wigley or Colonel Gusswalde had been subject to *fits* (no matter of what kind), before the policy was concluded, they would find for the defendant.

Holding these two (suppressed) truths in view, I now proceed to state, that the original of my report was in court both days, under charge of Mr. Tanner, from the Army Medical Board Office, who was specially subpoenaed for the occasion, and that had it been called for, would have proved that, "having carefully examined Captain W., I found that he had been labouring under epileptic fits, followed by delirium."

That any one should read this and say that

it is loosely or ambiguously worded, is really wonderful; but that when read in connection with my report (which it ought to have been, and it was no fault of mine that it was not), it should be deemed contradictory or obscure, is somewhat marvellous. Every word of the certificate was formed from the same memoranda from which the report was drawn out many months after, and when every circumstance connected with Captain W's. accident was fresh in my memory. I arrived at Macclesfield on the 16th May, in the morning of which day Captain W. first awoke calm and rational, and free from delirium; and whoever will read the report, must observe that I not only state every point that was related to me by those worthy of belief (and whom I would sooner believe than your correspondent), but I also state the condition in which I found Captain W. on my arrival at Macclesfield. I am quite ready to admit that the certificate did not contain all that the defendant's counsel could have wished—*et hinc illæ lachrymæ*; and that my explanation of that document was still less favourable to them; but none except those blinded by prejudice, or some worse motive, can peruse my report (on which was founded the certificate) and deny that my examination was a careful one. I fearlessly appeal to the evidence of Captain Mackay, Mr. Cockson, and the daily register of the late Mr. Newbald, in confirmation of every word of my report, and certificate also. The daily register of Mr. Newbald contains an entry, stating that he had attended Captain W. for "convulsive epilepsy;" and I may here add that I was informed by Captain Mackay (if I recollect right), that Captain W. had foamed at the mouth. If a person falls down suddenly, is convulsed, insensible, and foams at the mouth, there can be no doubt of such an attack being epileptic; and of the truth of all this I was convinced when at Macclesfield; but as already stated, it was of no consequence whether the fits were epileptic or not—at least as far as entitled the defendant to a verdict. I now come to that part of the certificate which states, "in consequence of a fall on the head." The effect followed the cause so soon as, in my opinion, to establish the close and intimate connexion of the one with the other; and that the fits were independent of any predisposition is more than probable from the fact, that no one ever saw or heard that Captain Wigley had fits during or after a long and fatiguing field day, a long and fatiguing fox-chase, or a long and fatiguing day's shooting; causes which are fully capable of exciting fits in the predisposed. But as if to strengthen and confirm every word of this, in steps the surgeon of the regiment to which Captain W. belonged, and with which he had served nearly two years in the Mauritius. Mr. Kell's interesting evidence proved that Captain W. was in the habit, whilst in that island, of taking frequent vio-

lent and long continued exercise in the sun—all the while eating and drinking the same as other officers (and all know that officers drink much more in a tropical than in a temperate climate), and yet, wonderful to relate, and in spite of being thus exposed day after day to the most powerful exciting cause of fits known, so wicked and perverse was this poor epileptic, that he would not even out of compassion to counsel for defendant, take one single little fit. This was an *esprit de corps* that would have annoyed the patience of the most learned in the land.

However, in order to prove that frequent and long exposure to a tropical sun, aided by good eating and drinking, is the most powerful exciting cause of fits known, I beg to refer your readers to the 2nd vol. of Cooke on Nervous Disorders, after page 211, and also to lay before them the following indisputable fact, viz. in the king's troops in India, i. e. in Bengal, Madras, and Bombay, there occurred, during a period of five years, of phrenitis, 138—epilepsy, 448—and apoplexy, 196 cases—making a total of 772 cerebral affections, all, or nearly all, arising from insolation and intemperance, or both combined.

Had I refused to certify, Captain W. must have come to Nottingham for re-examination, which would have taken that officer more than forty miles out of his way—a risk I did not choose to run, in his then weak and debilitated state. The extract from the Annual Report for 1827, proves that the certificate was granted on the testimony of others worthy of being believed. Does your correspondent mean to assert that an army surgeon, in the discharge of his duty, is to put no faith in the testimony of his brethren in civil life; and that when both meet together (as they often do) almost in the chamber of the sick patient, is the former to disbelieve the statement of the latter? Does your correspondent mean to reduce the veracity of the profession on such occasions to so low an ebb as this?

But to return to the certificate on which so many foolish hopes were hung. I am aware that if the words “from report” had been introduced after “I find,” it (the certificate) would have suited those of the most fastidious taste; but even with the addition, the learned in the law might perhaps have been dissatisfied, such is their ingenuity in picking holes in every thing that can be spoken or written. However, I maintain that it required no mending, for when read in connection with the report, the most obtuse in intellect may understand it.

I shall now show that the statement given of my evidence is false and full of omissions. In the first place, why were the two truths stated by the learned judge to the jury concealed; and why did your very moral and upright correspondent not inquire into the nature of the evidence withheld, before he indulged in aspersing the character of

another? Why is the daily register of the deceased surgeon not mentioned? and lastly, why is my own evidence suppressed? It is totally false that I appeared to give evidence on any one side in particular; I was subpoenaed by both parties (not even accepting the usual fee from the defendant), and I stood in court an impartial and unbiassed witness, ready and willing to answer to the best of my belief and recollection (after eight or nine years) such questions as counsel were pleased to put to me, and for no other purpose whatever. If your correspondent, when he states the certificate was “got up,” means to imply that any unfair or improper influence was used other than honest ones, or such as were agreeable to the rules of the service, he again states that which is false. The certificate was granted and worded for the information of a soldier, and not for the purpose of being twisted and misconstrued by a legal disputant, however high his knowledge of the law may be; nor was it worded to please the palate of the Eagle or any other insurance office in the kingdom. Is it not usual for those of reputation in the profession to prescribe for the disease of a patient who at the time is many hundred miles off, and who, perhaps, has never been seen? and if prescribe, why refuse to certify? Will your candid and veracious contributor explain (if he can) the legal and moral difference of these two acts, and which he deems the most criminal? if, indeed, there can be any thing culpable in one or the other, when the ground or authority on which both are done is not to be questioned.

Your readers are now asked, what is their opinion of him who conceals truth, and states that which is false, while he at the same moment talks of morality? Of your modest correspondent's valedictory advice!! I shall make short work, by throwing it to the winds, to be carried to and fro with bodies like itself light as air, and as insignificant and empty as the soap bubbles of a school-boy. Let me, however, warn your contributor, when he next attacks the character of another, to pay some little regard to truth, as a good cause requires nothing more.

I remain, Sir,

Your most obedient servant.

London, M. ALEXANDER, M. D.,
July 29, 1835. Staff Surgeon.

The following is the answer to my communication (of which that I now forward is nearly a copy) as contained in the notices at the end of No. 44 of the London Medical Gazette.

“*Dr. Alexander of Macclesfield.*—In reference to the letter respecting the insurance case, we have only to repeat what we said last week, that our account of the trial (false) was taken from the Times of the 13th ult., and to add, that at the time we wrote, we knew nothing more, either of the facts or

parties concerned, than appeared in the columns of that journal. It is too absurd to charge us with not noticing certain documents that were not even produced in court."

Now, nothing can equal the base and mendacious conduct of a journal which, while it admits into its pages false statements affecting the character of another, refuses to give a place to his defence. Such conduct requires no further remark—it speaks for itself.

The London Medical Gazette states that they copied from the Times of the 13th ult. Nothing can be more impudently false, for that journal (dates excepted) gives one of the truest accounts I have yet met with of my evidence. It is through the Times and another document, viz. one of the most correct (short hand) statements that exists of the trial (executed at considerable expense) that I am enabled to confound the writer on policies of life assurance, and contradict him on his own ground. In the Times, and the document just mentioned, not one word is stated of my "being obliged to confess having given a certificate without the requisite caution;" hence the inference is that that assertion is as false as the others mentioned.

11, Green Row, Chelsea. M. ALEXANDER, M. D.
Staff Surgeon.

—o—

MANUAL OF OPERATIVE MEDICINE, BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

1. *Capillary hæmorrhage* may be stopped by pressure, either by the fingers of an assistant, in the case of a small wound, or upon the mass, when this is large. Commonly we form, with little bundles of charpie or discs of agaric, a sort of pyramid, applied by its base upon the bleeding surface, and retained there by a bandage or appropriate apparatus.

Other kinds of plugging may be resorted to, and styptics and caustics may be united with compression. We have seen a case of capillary hæmorrhage from four wounds of the leg and thigh, which we were unable to stop, except by compressing the femoral artery on the pubis.

2. *Venous Hæmorrhages*.—Veins seldom lose much blood after operations, except in the two cases before mentioned. It is generally sufficient to compress their orifices for a few minutes with the finger. If the bleeding continue, we may apply the same methods as are employed for capillary or arterial hæmorrhages.

3. *Arterial Hæmorrhages*.—There are no less than fourteen methods for arresting hæmorrhage from the open mouth of an

artery, which have now, or formerly, had three approvers.

1. *The Expectant Method*.—Here every thing is entrusted to nature. It is important, however, to examine what occurs. J. L. Petit taught, that hæmorrhage is arrested by the formation of a clot of blood, of which the internal part, of a conical shape, and free in the arterial tube, was called the plug. This was united at its base to the outer portion of the clot, and was called the *covercle* (coverlid). Moreau explained it by the retraction, and the contraction or puckering of the artery; Pon-teau, by the swelling of the cellular tissue around the circumference of the extremity of the divided artery. These three theories prevailed over all others until the time of Jones, who ascertained that all these circumstances contributed to the obliteration of the vessel, and to the provisional suspension of the hæmorrhage. Afterwards the cut extremity of the vessel exudes coagulable lymph, in sufficient quantity to separate completely the internal and external clot, and to form that which Jones calls the third clot. To these causes Koch has added the double influence of a particular action of the blood, which renders it obnoxious to flowing through a divided vessel (in the same manner as it ceases to flow in the umbilical arteries when the cord has been divided); and of a want of suction on the part of the capillaries, arising from the removal of the part in which the terminations of the arteries take place. Thus, after amputations, Koch does not interfere in any way with the orifices of the vessels; but, as he employs an indirect means of compression, he cannot be said to employ pure expectation.

2. *The Method by pulling down the Artery*.—This is rarely applied to the arteries but in removing some tumours, the connection of which threaten to lose much blood; it is a useful means of securing retraction of the vessels.

3. *The Method by Bruising*.—Ledran having observed that the females of certain animals bit through the cord, and concluded, that it was the bruising caused by the teeth that hindered the hæmorrhage. He, therefore, bruised with the forceps the spermatic artery, in the removal of the testes, and succeeded. Jones has demonstrated, that bruising acts upon the internal coats of the artery, tears them, and that their flaps serve to arrest the blood, and favour the formation of the coagulum.

4. *The Method by Folding the Artery*.—A small part of the divided artery is denuded and folded upon itself. It has been advised for the intercostal artery, and has succeeded on arteries of small size.

5. *Styptics*.—It was formerly advised to insert small pegs of alum, sulphate of copper, &c. into the orifices of arteries, like corks. This method is justly fallen into

desuetude with regard to caustic applications, agaric, and other astringents; it is enough to say, that, however efficacious they may be when applied to the smaller vessels, they are quite inefficient in regard to the larger trunks. Cobweb and amadou, moreover, adhere in such a manner that they are not detached except with difficulty, and after a considerable period. Sponge is worse. Dupuytren has often been obliged to separate portions of this substance, in layers, with the forceps and scissors. Resin, also, when it becomes combined with blood and charpie, forms hard, irregular lumps, which irritate the tissues they are in contact with.

6. *The Method of Cauterization.*—This is only to be done by the actual cautery. For the application, we have before given the necessary rules. It is uncertain as far as regards the larger vessels. For the lesser arteries, it is a valuable means of resource, and we shall speak of it again in our description of many operations.

7. *Mechanical Plugs.*—We have already seen that cones of alum, sulphate of iron, &c. were formerly introduced into arteries; but their astringent action only was then reckoned upon. A long time ago wax, also, was employed to obliterate the arteries of the teeth, or such as had retracted into the interior of bones. Some different analogous procedures have been tried on the arteries of soft parts:—1. Wax. This being introduced under the form of a very delicate stick, the operator pinches the end of the vessel, and thus raises a knob of that soft substance within the vessel, which the blood has much difficulty in expelling. 2. A stylet, which Chastanet made use of to irritate the inside of an artery (Velpéau). 3. The catgut, or bougie, which M. Miguel d'Amboise tried upon dogs, introducing it about an inch deep into their arteries. In these it produced early and constantly a morbid action, which incapacitated them from receiving blood, although they were not mechanically obliterated. This method, combined with a ligature placed over the stuffed portion of the artery, may perhaps be useful in cases of ossification of the arteries. But M. Mance, who has made several experiments on this subject, has always found the internal clot, formed around the foreign body, fall into a state of putrefaction soon after its formation, so that hæmorrhage comes on unless a long and solid clot be formed between the foreign body and the next collateral branch above it.

8. *Direct Compression.*—Petit directs this to be made, in urgent cases, by the fingers of assistants, who relieve one another by turns, or sometimes by means of a particular apparatus. It is commonly united with cauterization; or, in the flap operation, it may be conjoined with folding back the artery.

9. *Indirect Compression* is applied on the

course of an artery, and usually with a tourniquet. It is the securest plan to join with this, for a short time, direct compression; we thus favour particularly the formation of a coagulum. After this manner Koch proceeds after amputations, as will be seen in the following description. The limb being removed, the operator places the flap on the wound, and maintains it by agglutinative bandages. A longitudinal compress is fastened along the course of the artery by a single bandage. The stump is placed in an elevated position, and a gentle pressure made upon it by the hands of an assistant for one or two hours, or as long as strong pulsations remain. When these have ceased, and the dressings are tinged red by the lymph which has exuded, all danger of consecutive hæmorrhage has disappeared, provided the patient remain quiet (Koch). The exudation soon ceases, and the dressings become cold, stiff, and dry.

10. *The Method by Ligature*, described by the ancients, revived by Paré. This method comprises several modes of proceeding, which vary according to the parts comprehended with the artery in the ligature, the materials of which the ligature is made, the manner of securing it, and the manner of disposing of its ends.

1. With respect to the parts comprehended in the ligature, A. Paré seized the veins and arteries, a portion of the muscles or other circumambient parts, and tied them altogether with a double ligature, thinking that thus the union of the vessels would proceed with more certainty and security. Dionis passed the thread into the flesh by means of two curved needles, and sometimes embraced at once even the vessels, the soft parts, and the skin. Desault was the first in France to recommend tying the artery alone; however, when the vein was close to it he tied them both together. At present the *immediate* ligature, or that which embraces the artery only, is generally preferred.

2. With respect to the materials of which the ligature is made. At first thread, single or double, was used. Ruysch proposed thin strips of leather; Veitch and Lawrence, very fine silk; Physick, fine strips of doe-skin; he proposed also metallic ligatures; others the web fresh from the silk-worm, catgut, &c. In France we prefer single or double thread, or narrow tape for the larger arteries.

3. With respect to the instruments employed. The *bec à corbin* of Ambrose Paré has given place to the dissecting forceps and *valet à patin*, revived with slight modifications under the name of the *fixed* forceps of Graefe or Amussat. Straight or curved needles are used. The tenaculum of Broomfield has been in vogue for some time past. Samuel Cooper recommends a double tenaculum; Columbat has constructed a very ingenious forceps which serves at once to

seize the vessel, place, and tie the ligature. Such instruments are too complicated for general use*.

4. With respect to the manner of fastening the ligature. Dionis cites two remarkable modes of proceeding; one in which the ligature was tied upon a small compress, and which, applied to aneurism, has lately obtained the name of Scarpa's method; another which consists, after the artery has been embraced, in traversing it from side to side with a ligature, previous to tying that—a plan revived by Astley Cooper. Jones employed the finest possible ligatures, and tied them very tightly in order to cut through the internal coats of the artery. Jameson prefers to use thin strips of doe-skin, moderately tightened, to act upon the same coats.

5. With respect to the *time* which the ligature should be continued, Jones and Travers pretended that a ligature applied for six, twenty, or fifty hours, and then removed, was sufficient to obliterate the artery; this was called the *temporary* ligature. The majority of surgeons in the eighteenth century permitted the ends of the ligature to hang out of the wound, in order to pull it away when the division of the artery should be effected. At present one end of the thread is cut off close to the knot, and the other only left to hang from the incision. Veitch, in 1806, proposed to cut both ends close to the knot, and to unite the wound, leaving the ligature to the efforts of nature. In order to favour abortion, when this method is used, animal ligatures are resorted to.

In *estimating the value* of these methods, it is to be observed that surgeons are divided upon two systems. One party, with Jones, pretend that to hasten the adhesion of the arterial walls, the internal coats should be divided; another, to which belong Crampton, Scarpa, and Jameson, declare this precaution useless, or even injurious. There are facts for and against both theories. On the one hand, ligatures which are too fine may cut through the artery before the adhesion of the coagulum and obliteration have taken place; whilst ligatures too lax are sometimes driven off by the impulse of the blood. We ought, therefore, to choose ligatures proportioned to the size of the artery, and tie them with just sufficient firmness to prevent their being thrown off. We should comprise no other parts with the artery, except when this appears diseased, for then it is liable to be divided too readily. In such a case, as we have before mentioned, the vessel may be tied upon a foreign body placed within it. With respect to the materials to be employed for a ligature, when we do not propose to unite by the first inten-

tion, the question is unimportant. When this union is attempted, the case is different. Then we find that the hanging out of the ends of the ligatures hinders cicatrization, and that vegetable threads, if left in the wound, give rise to consecutive abscess. Metallic threads appear to remain in the body without producing inconvenience, but they have only been tried yet upon dogs. We should prefer, therefore, doe-skin, not soft, as Jameson advises, but twisted, as Physick and Dorsay employ it. This cuts the internal tunics as vegetable thread would do, and is readily absorbed; consequently, both extremities may be cut close to the knot. Those who prefer vegetable thread must leave out one end, and not remove it until, having quite divided the artery, it is ready to fall out of itself. These preliminary observations having been premised, let us proceed to the manual operation.

In employing the *immediate* ligature, the surface of the wound having been sponged, the surgeon proceeds, guided by his recollection of the situation of the vessels, by the sight of the bleeding points, which the removal of the assistant's fingers discovers, or by the jet of blood made by relaxing the compression on the arterial trunk, to seek the arteries. He seizes each of these with the forceps, placing one blade on the outside, the other in the interior of the vessel (Des-sault); or he lays hold of it obliquely, so as to flatten its sides between the blades. He then draws out the vessel a little; an assistant passes a thread under the forceps, ties it once slightly, and holding its extremities tightly in the palm of the hand, with the three last fingers, he extends the index-finger of each side along the thread, so as to place their dorsal surfaces in opposition, directs the ligature beyond the forceps on the artery, and then, by separating the threads by the pulps of the index-fingers, makes the knot. On this another assistant places his finger, to prevent its becoming loose while the second tie is made in the same manner, and the knot completed. Now only does the surgeon relax his forceps; he has the compression removed, in order to satisfy himself that the artery is completely stopped, and proceeds to search for the other vessels.

When the arteries retract themselves deeply in the flesh, or under aponeuroses, it is requisite to divide these parts.

The forceps are only useful to take up large arteries, and then perhaps the tenaculum is preferable. The latter instrument is almost always required for small arteries. It is used by passing its point across the artery, in order to perforate its walls. The ligature is then applied in the ordinary manner already described. The tenaculum always takes up with the artery a little of the surrounding cellular tissue.

In a similar mode are used the *valet à patin*, the forceps of Amussat or Graefe. These being closed by particular mechanism are

* The attentive reader will observe that the author omitted, in his preliminary enumeration of the circumstances that make the method by ligature vary, this head.

very useful when the surgeon, having no assistant, is obliged to tie the ligatures himself.

The surgeon who employs the *mediate* ligature passes the two ends of the thread through two curved needles. He buries the first of these in the flesh, about half a line from the artery; passes it at about two or three lines above this, and brings it out on the opposite side. He makes the other needle describe a semicircle in the opposite direction. The vessel is thus completely surrounded, and nothing remains but to tie the ligature. One needle may serve to make the two semicircles in succession.

11. *The Method by "Refoulement"** (Amussat).—It consists in seizing the artery in a transverse direction with a pair of forceps; then, with another pair, called *pince à baguettes*, the blades of which, instead of being indented, are cylindrical, the artery is to be pinched above where the first pair were applied. This pinching suffices to break the internal coat; then the "*pince à baguettes*" are drawn from below upwards along the vessel, so as to push back the internal membranes, which burst into several pieces. The blood arrested by these pieces forms a coagulum more quickly than usual, and the coagulum obtains more numerous points of attachment than ordinarily takes place. *Refoulement* has been employed with success on dogs, but has only once been used on man. This was in a case of aneurism, and it did not succeed.

12. *The Method by Torsion*.—Vaguely indicated by Galen, re-discovered by M. Amussat, claimed by Velpeau and Thierry, torsion reckons at present many successful results.

M. Amussat's procedure. The extremity of the artery is seized with the fixed forceps, and is drawn out about five or six lines. With a common forceps the surrounding tissue is detached and pushed back towards the wound. Then, while the thumb and fore finger of the left hand fix the origin of the artery, the right hand is employed to give the forceps five or six turns on its axis, and the operation is finished.

The torsion may be continued to such a degree as to break the artery and separate the portion contained in the branches of the fixed forceps, but this is unnecessary. In order to prevent the twisted artery from protruding beyond the surface of the wound, it is sufficient to fold it backwards towards the wound.

M. Thierry's Method.—He is contented to seize the end of the artery with a pair of common forceps, or the *valet à patin*, and turn it round five or six times. The first mode of proceeding is the best. Amussat

has observed, that when the artery is not fixed, the torsion is extended as far as its next collateral branch. M. Velpeau also fixes the artery either with the fingers or with a second pair of forceps, as M. Amussat did at first. Velpeau turns the artery on its axis from three to eight times.

Torsion ruptures the inner coats like a ligature, but to a greater extent, and forces their debris into the inside of the vessel. The coagulum is perfectly arrested by the cap which the external twisted coat forms; and when the artery is sound, torsion is preferable to ligature.

13. *The Method by Seton*.—M. H. Jameson proposes to traverse the vessel with a seton of doe-skin, two or three lines thick; his experiments in this way, with dogs, having been perfectly successful. M. Carron du Villards obtained the same success by traversing the artery with a metallic or vegetable thread. We have before seen, that Dionis and A. Cooper have united this method to the ordinary ligature; and, notwithstanding the reprobation of many surgeons, we believe it to be a subject that deserves serious attention, and new experiments.

14. *The Method by Pinching*.—Temporary ligatures having succeeded in some cases, it was tried whether the rupture of the inner coats, repeated several times in a short portion of the course of an artery, would obliterate it. Maunoir, in 1820, invented, for the purpose, a forceps without teeth, which had a considerable resemblance to the "*pince à baguettes*" of Amussat. M. Carron du Villard, also, succeeded by this method in animals; but M. Amussat has made very numerous experiments, without once obliterating the artery. Hence this method *alone* should be rejected; but, united with the ligature, it promises the happiest result. M. Amussat conducts the united operations as follows:—The ligature having been applied, the artery is seized transversely above it with the "*pince à baguettes*," and the internal coats broken, through all their circumference, without injury to the outer coat. One, two, or more pinches may be made. The ligature only serves here to favour the formation of the coagulum; but the remarkable circumstance is, that the coagulum adheres firmly to the artery, at every point, when the internal coats have been divided. This method, which is quite new, appears to us well worthy to be investigated. If its efficacy should be confirmed on the human subject, we have no doubt that it will be substituted, at some period, for all others, at least with regard to the great arterial trunks.

* *Refoulement* means here a ramming or forcing back—no English word presenting itself to my recollection equivalent to the expression, this has been retained.—T.

Reviews.

A New and Complete Manual of Auscultation and Percussion, applied to the Diagnosis of Disease. Translated from the French of Dr. Raciborski. By W. Fitzherbert, B.A.

WE have much pleasure in introducing this Manual in its English garb; our readers will remember our notice of it previous to the appearance of any translation. An analysis of, or any extract from it now would therefore be superfluous. It far excels any of the *attempts* that have been made in this country to bring into a brief space the numerous and important diagnostic signs furnished by the stethoscope; and it moreover includes the auscultation of the abdominal viscera, as well as those of the thorax. If our readers follow our advice, they will possess themselves of it, and by it obtain an easy acquaintance with an extensive subject.

The translator has been somewhat too faithful, having put almost word for word, instead of compressing the exuberant French idiom into our compact and striking English expression. We would remind him, too, that there is not much of good taste in dedicating a *translation*, even though it be to an "M.D. Cantab." and a train of "&c. &c." We venture to say he will not repeat the dedication in any translation he may hereafter make.

—o—

SLEEP.

SLEEP may be defined as that state which is intermediate to life and death. The mental functions become fatigued by long continued action, and the natural remedy for that fatigue is sleep.

"—— the innocent sleep——

Sleep that knits up the ravell'd sleeve of care,

The death of each day's life, sore labour's bath,

Balm of hurt minds."

Sleep may be induced by many causes—such as swinging, by heat, cold, the murmuring of a stream, the ticking of a clock, or any other monotonous sound. Boerhaave prescribed for a patient on whom narcotics had not the desired effect, the dropping of water on a brass pan—this lulled the individual to sleep. Bichat divided life into organic and animal, the first performing those functions which nourish and sustain the body, the second making the animal a sentient being. He considered the first went on, and that the second was suspended in sleep. It is probable that in sound sleep

it is so; but in the state of slumber, or when sleep is not very profound, we may hear and feel, and the impressions thus caught often form the basis of dreams, by that mysterious power of association which the minutest object may bring into action. All animals sleep—in man much depends on habit—it may be kept off a considerable time by stimulants. It is said that Voltaire formed a club, the members of which were to do without sleep; they kept themselves awake for several days and nights, by means of strong tea and other stimulants, but they were beaten at last, and were obliged to sink into the arms of the very *friend* they had treated as an *enemy*. Napoleon Bonaparte, General Elliott, Frederick the Great, and the illustrious surgeon, John Hunter, may be mentioned as a few among the many who did with the small quantity of sleep necessary for recruiting the strength; on the other hand, Parr slept away three parts of his life, and de Moïtre five-sixths of it. Soldiers have been found asleep on the field of battle, and I believe it was at Trafalgar some boys were found fast asleep under one of the most active guns of the squadron. Shakspeare, too, has spoken of the "ship boy's eyes" being closed

"Upon the high and giddy mast,
And in the visitation of the winds."

Sleep differs in various persons as to profundity, and it differs also during the night. It is generally heaviest during the first five hours, and becomes lighter towards morning. Hence we often find morning dreams more consistent than others. Children and persons of little reflection generally sleep soundly. Health and disease also modify sleep; the one being full of tranquillity, the other feverish and unrefreshing. The author of Night Thoughts has spoken of sleep forsaking the wretched, and

"Lighting on lids unsullied by a tear."

I question whether a subdued feeling of melancholy is inimical to sleep—indeed I think it rather tends to the inducement of that state—so no doubt does a feeling of contentment; on the contrary, all violent emotions, whether of joy or pain, are inimical to repose.

Deep sleep has been called "the image of death;" Shakspeare has thus made Jacchimo speak thus in the chamber of Imogen: "Oh sleep, thou ape of death, lie dull upon her,
And be her sense but as a monument
Thus in a chapel lying."

Keats, too, has beautifully described the progress from slumber to deep sleep, in his exquisite "Eve of St. Agnes;" when he speaks of Madeline when quite asleep, he says she is

"Blinded alike from sunshine and from rain,
As though a rose had shut, and was a bud again!"

With regard to the state of the mind and body in sleep, the following epigram appears to me very expressive:

"Come, gentle sleep, attend thy votary's prayer,
And, though death's image, to my couch repair;
How sweet, though lifeless, yet with life to lie,
And without dying, oh! how sweet to die!"

—

MEDICAL REFORM BILL.

ON Monday last, Mr. Warburton presented a petition from forty-eight licentiates of the College of Physicians, against the revised code of by-laws lately promulgated by the College, which the petitioners described as not only unjust but illegal. Mr. Warburton, in supporting the petition, said that the new by-laws were not only most illiberal but altogether unwarranted by law. He informed the house that Mr. Wilcocks, who had made the subject of medical jurisprudence the peculiar object of his studies, gave it as his unqualified opinion before the Medical Committee of the House, of which Mr. Warburton had the honour of being Chairman, "that the Charter of Hen. VIII. having laid down no such rule for perpetuating this corporation, the College had no legal right to set the restrictions complained of, but were bound to examine licentiates, and judge of their claims to admission by their actual qualifications, and not with reference to the place at which they have been educated."

Mr. Wakley supported the petition, and declared his full conviction, founded upon long experience and examination of the subject, that the College of Physicians, so far from having promoted the honour or dignity of medicine, or raised the character of its professors, had been, ever since its incorporation, a mischievous incubus. He trusted that

Mr. Warburton would occupy his leisure during the recess, so as to be able, on the opening of the next session of Parliament, to bring forward a measure founded on the Report of the Medical Committee, putting the profession on an entirely new footing.

Mr. Warburton said he would have brought forward the measure alluded to, but for two interruptions. First, the burning of the House, which involved the destruction of nearly two-thirds of the printed evidence of the Committee, which had consequently again to be written out from the short-hand notes, and printed; and secondly, the breaking up of the Ministry. He trusted, however, that in the beginning of next session, he should be able to fulfil the honourable Member's wishes.

We stated in No. 178 of this Journal (July 11), that "the new regulations of the College of Physicians were of little value, and cannot render the College popular or increase its friends." Our prediction has been fulfilled. The proceedings above detailed must be gratifying to every independent reformer, as medical reform is certain. The tone in which Mr. Warburton exposed the impolicy of the new by-laws shews the mind of that gentleman towards all medical corporations. It is manifest that he is determined to reform and place the profession on a totally new footing.

Mr. Wakley's designation of the College of Physicians as "a mischievous incubus" on the profession, was most appropriate. Had the College done their duty at any single period since their incorporation, neither the College of Surgeons nor Apothecaries' Company could have arrived at the head of the profession.

But the College of Physicians were to be most exclusive; and such is their consummate folly, even when the arm of the law is against them, that they cannot ward off the blow by the adoption of liberal and pacific measures. Their

bad example, has always been followed by every other medical corporation in the United Kingdom, and hence the necessity of reform in every one of these bodies. They surely cannot expect to escape when the municipal corporations are undergoing those salutary changes which the public have required. Nevertheless the Colleges of Physicians and Surgeons, having great interest at court, are so insane as to imagine they can frustrate the decision of the House of Commons, though passing events have clearly demonstrated that the time for such influence is gone by.

It appears to us that efficient medical reform is certain, and we have no doubt but that it will be based upon sound principles. We have reason to know that a good preliminary education will be required of those intended for the medical profession; that there will be a Metropolitan University for granting degrees; that there will be one faculty in each section of the empire, and that medical education and practice will be materially improved. It is quite certain, that the career of the British medical corporations approaches its end.

We feel convinced that Mr. Warburton's intimate knowledge of the continental system of medical education and practice, and of that of this country, will lead him to propose a measure suited to the wants of society, and beneficial to the interests of the profession. He will doubtless change the hospital system, the election of collegiate councils and professors, the appointment of parochial medical officers, the education of chemists and druggists, and the remuneration of general practitioners by fees.

It is also certain that there will be an obstetric examination board, and this will be chosen from the ablest obstetricians, physicians, and general practitioners in this capital, and from the most eminent of Dublin and Edinburgh physicians, and surgeons. It is perfectly certain that any reform will render the profession much more beneficial to the public than it is at present.

The medical profession are deeply indebted to Mr. Warburton for his Anatomical Bill, and we have no doubt but his medical reform act will transmit his name to the future medical historian as a sincere friend to humanity and medical science.

Hospital Reports.

WESTMINSTER HOSPITAL.

Acute Eczema Impetiginoides, treated successfully, followed by Abortion, leading to fatal Puerperal Peritonitis. With post-mortem Examination.

SARAH HALSEY, aged 43, a laundress from Codicote, Herts, was admitted July 21st, into Queen Anne's Ward, as a patient of Mr. Guthrie. She is a married woman, and has had ten children, nine of whom are living. During one of her pregnancies, nine years since, she was engaged in the fields making hay, when she scratched the right leg with a thorn, to which circumstance she refers the production of an eruption in the leg, which soon after appeared, and of which she has had frequent attacks since, all of them, however, being confined to the leg in question. Four months ago, without any obvious or assignable cause, a similar attack made its appearance in the same situation, which, however, has subsequently spread all over the body, except the face, which, as yet, remains free.

The eruption appears to commence in the form of minute vesicles, not larger than pin's heads, which are attended with an intolerable heat and itching. These vesicles break and discharge a thin, watery serum, numerous minute abraded surfaces are thus produced, which become confluent, and lead to the formation of thin, scaly crusts, many of which have a considerable resemblance to psoriasis, but are surrounded by a great degree of erythematous-like redness and inflammation. The crusts are at first mostly of a round or oval form, and when they fall off, or are removed by scratching or other means, the surface beneath them is found very red and irritable, and secretes an acid, irritating fluid. These naked and unprotected patches, many of them coalesce, and in this way very extensive surfaces on the trunk and extremities become as completely deprived of cuticle as by the application of a blister. In several places rather large, but irregularly shaped phlyzaceous pustules are seen, particularly where the eruption has made the most progress. The tout ensemble, at present, comes up very closely to the idea conveyed by Alibert's name for this affection—"darte squameuse humide." The itching and heat of skin annoy the pa-

tient very much. At the same time that the eruption appeared, the catamenia became irregular, and have continued so since; there being a very scanty "shew" at the proper periods. The appetite is very much impaired; tongue is furred; bowels constipated; pulse frequent, and there is great thirst. Mr. Guthrie has ordered her a warm bath every night, which she has had, and thinks they do her a great deal of good. She has also been taking the juice of the *menyanthes trifoliata*, in doses of half an ounce three times a-day. This, however, caused irritation of the stomach and alimentary canal, with vomiting; it was therefore diminished in quantity to two drachms three times daily, but it does not appear ever to have agreed with her.

August 1st. To-day there is some appearance of the eruption in the face, it being covered with minute elevations, like incipient vesicles. The rest of the surface is in as acute a state of inflammation as ever. The *menyanthes* has been omitted, by direction of Mr. Guthrie, and the following mixture prescribed:—

R. Liq. ammon. acet., $\frac{3}{4}$ iss;
 Liq. antim. tart., $\frac{3}{4}$ ss;
 Magnes. sulphat., $\frac{3}{4}$ ss;
 Mist. camphor., $\frac{3}{4}$ vj. M. ft.

Mist. capt. cochl. iij 4tis horis.

To have the surface moistened occasionally with thin gruel.

3rd. Continues much as before, but, if anything, the eruption is more aggravated than at last report, and presents more of the impetiginous character, from the presence of a greater number of pustules. She complains more of the heat of surface and itching; also of excessive thirst. The face is flushed and hot; tongue is very much furred; pulse 144, small, but strong. Mr. Hale Thomson, who acted for Mr. Guthrie to-day, directed the *magnesie sulphas* to be omitted in the mixture, as being likely to irritate the digestive canal. He also directed her to lose six ounces of blood from the arm, to continue the warm bath, and to have toast-water ad libitum.

4th. She feels much better to-day; there is much less itching, pain, and heat, both in the arms and legs, and the crusts are in many places desquamating nicely; the secretion of acrid serum appearing to be entirely suspended. The erythematous inflammation around the crusts is likewise drying away. The face is not so flushed, nor have the vesicles on it made any progress, but, like many others on the hands, &c., have disappeared, apparently by the absorption of their contents. The blood drawn yesterday was buffed. The thirst has a good deal diminished; pulse 140, and not so strong as yesterday. She complains of pain in the hypogastrium. An evaporating lotion has been applied to the arms, where there is most of the erythematous redness.

Contr. mist. diaphoret.
 Repr. baln. tepid.

6th.—On the evening of the 5th the pain in the hypogastric region increased, and she was seized with uterine hæmorrhage, which terminated in the abortion of a fetus at apparently about the fourth month. She altogether denies having had the least idea of being pregnant. The inflammation of the surface has now almost entirely abated, the acrid secretion has entirely dried up into crusts, which are now rapidly falling off, all over the body, leaving nearly a healthy cuticle beneath. Indeed, the very marked and rapid improvement produced by the bleeding is altogether surprising. Pulse 150, softer and fuller than before, tongue not nearly so furred, but still red and flabby, countenance flushed and somewhat anxious. Mr. Guthrie has ordered her a little arrow-root and wine, and such other restoratives as she can take.

8th. The eruption has now almost totally disappeared, by the desquamation of the crusts. During the last two days, however, symptoms of puerperal peritonitis have been present. There has been an insidious pain in the hypogastric region, aggravated upon pressure, with a considerable degree of febrile disturbance of a low adynamic type. Pulse 150, small and feeble; the surface in general is cold, whilst the face is flushed; countenance sunken and anxious; pupils dilated; there is complete anorexia, tongue is red, glazed, and intersected with fissures; sordes have collected about the teeth and lips, bowels have been costive, until she took an aperient yesterday, since which they have been relieved about twice daily; has had a great deal of sickness and retching, which still continue. She has rejected the effervescing draughts, with an excess of volatile alkali, which have been prescribed for her, but kept down a draught with a drop of hydro-cyanic acid, which Mr. Soden ordered her this morning.

Mr. Guthrie has directed her to have bladders filled with warm water applied to the abdomen, and an enema to be administered immediately.

9th. Yesterday afternoon, Mr. Guthrie saw her with Dr. Henry Davies, who prescribed the following:—

R. Hydrarg. submur., gr. xvij;
 Confect. opiat, gr. vj. M. ft.

Pil vj. Capt. tertiis horis.

R. Ammon. Carb. \mathfrak{z} j;
 Aquæ, $\frac{3}{4}$ viij. M. capt. cochl.
 Ampl. singula semihorâ.

The uterus was examined per vaginam, but no lesion of any description detected. She remains much as before.

10th. Does not complain of the pain in the abdomen; the countenance, though less anxious, is yet extremely sunken, and expressive of debility; the pupils are not nearly so much dilated. Pulse 120, extremely feeble; surface not quite so cold as on the 8th, tongue is still dry and glazed, has occasional hiccough.

App. Emp. canthar. amp. regioni hypogastric.

11th. This morning early Mr. Soden reports, the pulse was not perceptible at the wrist, and it is now (one P.M.) so small and feeble, as scarcely to be counted; tongue, &c. much as yesterday, feet cold, has no pain except from the blister. Has had a troublesome diarrhoea, the motions being passed involuntarily. She slept but little during the night; answers questions coherently. The calomel pills have been omitted. Has had a cretaceous draught, and small doses of ammonia and tincture of cardamoms, frequently repeated, as well as port wine.

12th. She gradually sank, and died yesterday evening about five P.M.

Post-mortem Examination.

We had not an opportunity of being present on this occasion, but the following is the report we have received:—The convolutions of the intestines were extensively adherent to each other, by recently effused lymph. There was from a pint to a pint and a half of sero-albuminous fluid, almost resembling pus, in the cavity of the pelvis. The uterus, with its appendages, were all in a state of great hyperæmia, especially the fimbriated extremities of the fallopian tubes, the internal surface of the uterus, and the os tinæ. It does not appear that the other viscera, so far as examined, presented any morbid appearances.

Observations.—This case presents many points of high interest. In the first place, taken in connexion with another case formerly reported from this hospital (vol. vii, p. 381), it not only seems to substantiate Rayer's observation of its greater frequency in females, to which he adds, "particularly at the critical epoch of life"*; but would seem to show, that irritation or derangement of the uterine function has more to do with the development of this cutaneous affection, than he even represents; for, in both these cases, there was uterine disturbance, and no assignable cause for the eruption. Secondly, the remarkable benefit produced by the venesection, and the unfortunate production of abortion, consequent on the repulsion of the eruption, but which no foresight could have prevented. Here it may be well to inquire, what was the cause of the abortion? Did the irritation of the alimentary canal, produced by the menyanthes, extend to the lower bowels, and irritate the uterus by sympathy of contiguity? Or, must we regard the abortion as solely consequent on the metastasis of inflammation from the skin to the uterus? We will leave our readers to solve these interesting questions; and will just remark,

in conclusion, that the occurrence of puerperal peritonitis, after abortion, is of so rare occurrence (and in this we are supported by Dr. Davies), as of itself to confer intrinsic interest on the case.

Inflammatory Phymosis, with general Erysipelatous Inflammation of the Genitals.

Wm. Barnett, aged 25, was admitted into Henry Hoare ward, June 23rd, as a patient of Mr. Guthrie. He has been suffering both from gonorrhœa and chancre, the former during six, and the latter during one month. He likewise had buboes in both groins. He became an out-patient at the hospital, and took blue pill three times daily, and applied the black-wash to the sore. About a fortnight previous to his admission, the gonorrhœa rather suddenly ceased. On the Sunday previous, without any assignable cause, inflammation came on in the prepuce, extending to the penis, the scrotum, and, in fact, to the whole external apparatus. Severe phymosis was induced by the præputial inflammation. There was great pain, heat, redness, and tumefaction. Fluctuation was distinguished in the left bubo, which was opened at the time of his admission, as well as the prepuce divided, by Mr. Hale Thomson.

24th. Much the same as yesterday. The urine deposits a copious sediment of the orange-coloured lithates.

25th. The inflammation in the genitals is more severe; the redness and tumefaction being of a red glabrous kind, having the erysipelatous character, and are attended with great pain. The erysipelatous blush extends to both groins, especially to the right, the bubo in which appears now to have suppurated. Mr. Thomson opened the bubo, and evacuated a quantity of pus. He also made an incision with a bistoury, through the integuments of the penis, from the root to the prepuce, and another, not so large, through those of the scrotum, on the left side, where the tension was greatest. These incisions produced a little bleeding, which seemed to give him a good deal of relief. Warm fomentations were afterwards freely applied.

26th. Says that he feels relieved by the incisions, and the inflammation appears less acute. He is directed to have lint dipped in the tinct. benzoes, comp. applied to the wounds, and a linseed poultice over this dressing.

Rx. Acid. sulphur. dilut., 3 ij;
Decoct. cinchonæ, 3 viij.

M. ft. Mist. capt. cochl. iij ter in die.

27th. The inflammation has been considerably subdued, there being neither the redness nor tension that existed previously to the incisions being practised. He states that he now feels very easy. Tongue is

* Rayer on Diseases of the Skin, by Dickenson, p. 89.

covered with a thick white fur, with red margins.

Hæbeat pulv. rhei c sodâ statim.

29th. The powder was repeated yesterday. Much better; tongue is less furred and red; appetite improving—he has enjoyed his dinner of broth to-day; bowels are regular; pulse 108, feeble.

July 2nd. Going on well, both locally and constitutionally; the inflammation has entirely lost every urgent character. The wounds left by the incisions are filling up with granulations, which, however, are somewhat flabby.

4th. There is a progressive amendment.

9th. The wounds in the scrotum and the penis are rapidly filling up, and the granulations have now a red, firm, and healthy aspect. The appetite is good, and the general health is improving. He continues the bark mixture.

11th. The local mischief is becoming rapidly repaired, and the patient gets quite stout. The dressings have been changed for simple cerat.

14th. Much better; tongue is slightly furred, the appetite good, and bowels regular. He continues the mixture.

21st. The incisions have now completely cicatrized, but a good deal of deformity from thickening of the tissues of the penis, &c. remains. The prepuce has closed over the glans, notwithstanding the precaution of sponge tents, had been resorted to during the cicatrization; so that the glans can only be seen through the contracted opening. Mr. Guthrie proposes a little operation to remedy this defect, as soon as it may be prudent to employ the knife on an organ, which has been, so recently, the seat of severe mischief.

28th. Discharged relieved, and placed on the books as an out-patient.

—o—

Foreign Medicine.

Cholera in the South of France.

THE last accounts state that the scourge had diminished at Toulon, but was on the increase at Marseilles. On the 23rd of July the deaths, at the latter place, were 134, of which 129 were by cholera; on the 24th the deaths were 105, eighty-nine of which were by cholera. At Toulon the last bulletin only mentions seventeen new cases, and twelve deaths. It continues at Aix, and has appeared at Draguignan le Luc, Antibes, Lorgues, Nice, and Villefranche. There was a report of its having broken out at Beaucaire, but this would appear to have been premature. Nîmes, Montpellier, and Avignon, are still healthy. The disease seems as if unable to leave the sea-side; it has even been observed to lose much of its intensity as it advances inland in a radius

of at most two leagues from the coast about Toulon, which is the focus of the infection. Ice appears to have been the most efficacious remedy; it is swallowed in lumps. The practitioners at the above places are using against the choleric evacuations, glysters composed of prepared tannin, tincture of ratanhy and laudanum.

—o—

Case of Permanent Contraction of the Cremasters.

FRANÇOIS D., residing in the suburbs of Bordeaux, aged 62 years, while in the act of copulation, heard a violent noise at the door of the room. The surprise, the fear of being discovered in such a situation, but more than all, the sudden interruption of the act, produced an immediate tremor of the whole body. Acute pains of the hypogastrium and groins came on, and continued notwithstanding several means that were taken. On presenting himself to a medical man five months after, the testicles were found to be exceedingly painful to the slightest touch: and they were drawn and held up towards the arch of the pubis, leaving the cavity of the scrotum empty. They were moreover strongly fixed to the arch of the pubis, and immediately in front of the inguinal canal, into which they appeared to be nearly slipping. The pain caused by this pressure against bony parts, obliged the man to walk constantly with his body bent almost double.

The treatment employed consisted in emollient hip baths continued for a long time; demulcent poultices on the painful parts; repeated applications of leeches along the course of both inguinal canals, and frictions of the same with extract of belladonna. After two months of this treatment the cure was complete. The almost tetanic contraction of the cremasters ceased, and the testicles fell again into the scrotum.—*Journal de Médecine pratique de Bordeaux.*

—

Minute Structure of the Muscular System.

Dr. Alexander Thompson read a paper to the Académie des Sciences on the 27th July, on the above subject, the conclusions from which are as follow:—

1. None of the abdominal muscles of the perineum, the pharynx, or the bladder,

stop at the median line. Their fibres not only pass the line to be fixed to the bones of the opposite side, but in so passing they become interlaced with the fibres of the corresponding muscles of the opposite side, making with them an actual interjunction.

2. There is no perineal aponeurosis, in the meaning of MM. Gerdy, Blandin, and Velpeau, the aponeurotic lamellæ being formed by the interlacing of the tendinous fibres of the muscles of both sides.

3. The cremasters are independent muscles, and not prolongations of the lower fibres of the small oblique of the abdomen.

4. The round ligaments of the womb are only a transformation of the cremaster muscles.

5. The *gubernaculum testis* is nothing more than the cremaster accompanied with the vessels and nerves requisite for a glandular organ.

6. There is only one series of muscular fibres in the bladder, and these are arranged in a spiral manner, cross each other before and behind, and then are fixed by the tendinous extremities to the articular edges of the symphysis pubis.

Influence of Temperature on Mental Alienation.

M. Boulteville, of the Lunatic Asylum of Rouen, states that in the six months from May to October of the year, the medium temperature is 15 deg. 79 C., and of the other six, from November to April, it is 5 deg. 9. He found—

1. That the admissions were by no means frequent in the hot season—there being a diminution of almost one sixth.

2. That the action of temperature is more decided in the exits than the admissions, for there are more discharged in the warm months than in the cold, by a fifth. As the period of discharge, even when it takes place previous to cure, coincides most generally with the favourable condition of the patient, it may be deduced that an elevated temperature favours their amelioration.

3. That cures are more frequent in hot than cold weather; the difference in the entire cures being as two to one, and in the most readily perfected cures, or in the first three months of admission, greater still.

4. That the influence of temperature on

the mortality is strongly prominent, but in the inverse ratio of the preceding; for the cold seasons correspond with the greatest number of deaths, and the difference reaches one third.

The greatest number of deaths occurs in the month of April; July that in which they are fewest. It sometimes happens that the patients will resist a short but vigorous frost, while they sink under a moderate but steadily continued cold. Hence the most fatal months are those which come last in the revolution of the seasons.—*Gazette des Hôpitaux.*

Ophthalmophantome.

M. Andrieux has invented a kind of bronze bust, moveable on a pedestal, the orbital cavity of which is adapted to the reception of a human or a pig's eye. This eye, by means of a metallic rod, is made to execute all the movements of the human eye between the eyelids. The instrument—to which the above name is given—is intended to afford the students an opportunity of performing the various operations on the eye, and chiefly that for cataract, the difficulties that present themselves in the living subject being still in great measure existent.

Intermittent Fevers.

The following are a few of the numerical facts adduced by M. Maillot, a French military surgeon in Africa, on the above subject. From the 9th of February, 1834, to 21st February, 1835, he had in his hospital two thousand three hundred and fifty-four distinct cases of intermittent fever. Of these, one thousand five hundred and eighty-two were quotidian, seven hundred and thirty were tertians, and twenty-six quartans. As regards the hour of the paroxysm, one thousand six hundred and fifty-two came on between midnight and mid-day, and six hundred and twenty-eight between mid-day and midnight: or, more in detail—

1. Of the one thousand five hundred and eighty-two quotidians, one thousand and ninety-nine came on from midnight to noon, and four hundred and ninety-three from noon to midnight.

2. Of the seven hundred and thirty tertians, five hundred and fifty were from midnight to noon, and one hundred and eighty from noon to midnight.

3. Of the twenty-six quartans, thirteen were from midnight to noon, and the same number from noon to midnight.

The great majority of attacks were from nine in the morning to noon, from ten o'clock to noon for the quotidianas, and from nine to ten for the tertians.

Of the seven hundred and thirty tertians, six hundred and seventy-nine returned on even days, and three hundred and sixty-one on odd days.

On the score of complications of the two thousand three hundred and thirty-eight intermittents, six hundred and fifty-eight were simple, and one thousand six hundred and eighty complicated: they may be subdivided into—1. Quotidianas, one thousand six hundred and seventy-six complicated, and four hundred and six simple: 2. Tertians, four hundred and eighty-eight complicated, and two hundred and forty-two simple: 3. Quartans, sixteen complicated, and ten simple.

Of the anatomical condition of the body; the spleen was found to be diseased alone, twenty-five times; the peritoneum alone, once; the encephalon alone, four hundred and sixty-eight times, and, of these, four hundred and twenty-five in an irritative form, and forty one in an inflammatory form. The spinal cord was diseased alone, once; the lungs one hundred and three times; the pleura, five times; and there was one case in which the only visceral complication or lesion found was an exudatory angina.—*Revue Medicale.*

GRADUATIONS IN MEDICINE AT THE UNIVERSITY OF EDINBURGH.

August 1, 1835.

(Concluded from our last.)

FROM ENGLAND.—Theodore Boisson, on Hypochondriasis; Hatton Turner Bowle, on Syphilis, with Remarks on the Mercurial and Antimercurial Treatment; Robert Chevallier Cream, on the Chemical History and the Physiological and Therapeutical Action of Tartarized Antimony; George Ebenezer Ely, on Dropsy; William C. Enlgedue, What evidence have we that the External Senses can be transferred to other parts of the body, as is said to occur in Somnambulism? William Chambers Evans, on Bronchocele; William Giffard Everett, on Epilepsy; Edward George, on Asphyxia from Submersion; John Griffin, on Varicose Veins; William Henry Hooper, on Delirium

Tremens; Charles Thomas Hamilton, on Erysipelas; Edward James, on Œdema of the Glottis; James Kendrick, on the dependence of Diabetes Mellitus on Disease of the Stomach and Intestines; Thomas Carey Laver, on Burns; David Lietch, on Respiration; William Macgill, on Retention of Urine; George Merryweather, on some of the Mutual Relations of the Atmosphere and Ocean; Richard Parnell, on the Causes of Death by Asphyxia; Astley Purton, on Croup; Frederick Row, on Phthisis Pulmonalis; John Glasier Seagram, on Pericarditis; Robert Shean, Observations on the most prevalent Diseases of British Soldiers in the East Indies, viz. Febris continua communis, Febris remittens, Biliosa, Hepatitis acuta, Dysenteria acuta; Thomas Henry Starr, on Diabetes Mellitus; George Strong, on Purulent Metastasis; James Surrage, on Puerperal Fever; Rowland John Traill, on the Modus operandi of Remedial Agencies in the Treatment of Inflammation; John Tucker, on the Physiological and Therapeutic Operation of the Solanææ; John Tunstall, on the Irregularities of the Secreting Function; John Knox Wade, some Observations on Disorders of the Intelligence; George Vaux, on Pathology and Treatment of Cerebral Apoplexy; William Wells, on Pericarditis; George A. F. Wilks, on the Nature of Respiration, and its Connexion with the Nervous System; Thomas Wilstrop, on Ascites; Peter Wood*.

FROM IRELAND.—Francis Anderson, on Ischuria Renalis; Thomas Andrews, on the Circulation and the Properties of the Blood; William Andrews, on Apoplexy; Samuel Bryson, on Peritonitis; Richard Woods Cooke, Practical Remarks on some Injuries of the Head; Joseph Henry Corbett, on Menstruation; Edward Paoli Drew, on Acute Hydrocephalus; Hugh Fitzpatrick, on the Pulse; John Fitzsimons, on Continued Fever; John Jeffries, on Aneurism; Richard Kennedy, on Rubeola; Francis James Lynch, on the Varieties, Consequences, and Treatment of Burns; Charles Mackay, on Phthisis Pulmonalis; Augustus Macculagh, on Syphilis; Patrick O'Connor Meade, on Hydrops Abdominis; William Lambert Methven, on Hepatitis; John Thomas Monypeny, on Ascites; John Morrison, on Inflammation of the Liver, and on the Seat and Connections of that Viscus; Edward Nevill, on Sensibility as a General Law of Organic Structure; Harward O'Farrel, on Iritis; John Peppard, on the Functions of the Brain; Joseph Samuel Prendergast, on Clap; Andrew Quinlan, on Aneurism by Anastomosis; James Reed, on Bronchitis; Robert Rodgers, on Aneurism; David Ross, on Injuries of the Head; James Ross, on Inflammation; James Maxwell Sanders, on Delirium Tremens; David Scannell, on Hy-

* Received his Degree on 22d November, 1834.

drocele of the Tunica Vaginalis; Epaphroditus Young, de Erysipellate.

FROM ABROAD.—Joseph Adams, Malta, on Delirium Tremens; Alexander Campbell, Persia, on Wounds of the Thorax; David Alexander Carnegie, East Indies, on Typhoid Fever; Thomas Clarke, Jamaica, on Capillary Circulation; Aaron Hart David, Canada, on Infanticide; William Marriott Finch, East Indies, on Pneumonia; John Llacayo de Pinteno, Spain, de Definitione seu Natura Febris; David Davidson Manson, New Brunswick, on Scarlatina; William George Prichard, East Indies, on Hypertrophy, with Dilatation of the Heart; William Roxburgh, East Indies, on Climate; John Smith, East Indies, on Uses of the Liver and its Secretions; Edward Quincy Sewell, Canada, on Dyspepsia; Stephen Charles Sewell, Canada, on Intermittent Fever; Henry John Tucker, Island of Bermuda, on the Relations of Life and Organization.

DISEASES OF THE GENITO URINARY ORGANS—NEW URETHRAL INSTRUMENTS.

WE this week present to our readers a modification of the urethral instruments lately introduced. These are Mr. Benjamin Phillips', but that gentleman has invented many others of great value, adapted to the different kinds of permanent stricture.

PLATE I. *Fig. 1.*—The model bougie, which is prepared in the following manner; an elastic gum tube should be chosen, the canal of which is lessened in capacity as it approaches the extremity upon which the preparation is to be placed. A mesh of cotton, such as is made use of in lamps, is attached to a piece of wire of sufficient length to traverse the tube.

This mesh should be sufficiently large, to completely block up the smaller end of the tube.

It is then drawn through the canal with sufficient force to become firmly impacted; a portion of the mesh is made to project much in the same manner as a lamp wick, and of the length of half an inch.

This projecting portion is then dipped into a composition formed of equal parts of diachylon, bees' wax, and shoemakers' wax. As soon as a sufficient quantity of the composition is taken up by the cotton, it is carefully kneaded, and when it has become nearly cool, it is rolled between two pieces of wood or stone, until it becomes of a nearly similar diameter to the rest of the tube.

Fig. 2 is intended to represent a strictured urethra, into which the model bougie has been introduced; it has taken the character of the orifice as well as of the anterior portion of the stricture.

Fig. 3. The model bougie, removed from the canal, bearing the impress of the stricture.

Fig. 4. It occasionally occurs that the orifice of a stricture is removed from the centre of the canal; in this case, we pass the instrument bearing the caustic, or indeed a small catgut bougie through this instrument, and are enabled, by the bolster at its extremity, to elevate or depress it at pleasure.

Fig. 5. A caustic apparatus: *a* the canula; *b* the instrument bearing the caustic.

Fig. 6. The portion of the instrument which bears the caustic: *a*, a platina tube; *b*, a canal composed of two-thirds of a circle, into which powdered nitrate of silver is placed; the heat of a spirit lamp is applied to the instrument, the caustic is fused, it is then suffered to cool, and we have a cylinder of caustic firmly impacted in the instruments.

Figs. 7 and 8. Similar instruments, curved.

Fig. 9. An urethra into which the cauterizing instrument has been introduced: *a a* the canal; *b b* the strictured portion: *c* the caustic instrument, with the caustic within the stricture.

Fig. 10. Similar to the former, except that the orifice of the stricture is not in the centre of the canal; here we see the utility of the instrument *fig. 4*.

PLATE II. *Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10,* are figures which were presented by the model bougie upon being withdrawn from the urethra; they are faithful impresses of the characters of certain strictures, to which allusion has already been made.

The figures under *figs. 7, 8, and 9,* and along side of *fig. 10,* are placed merely to shew more plainly the character of the canal in those several cases.

Fig. 11 is a model of a sound which is, as nearly as possible, adapted to the shape of the canal of the urethra in the adult; the length should be from ten to twelve inches.

Fig. 12 is the urethrotome introduced into a strictured canal: *a a* the canal; *b b* the strictured portion; *c* the stiletto, which has been pushed through the stricture and then

withdrawn as far as the obstacle, serving as a director and also enabling us to estimate the length of the stricture, the canula being against the anterior and the stiletto against the posterior part of the obstacle; *d* the cutting instrument, which is projected and has incised half of the induration; *e* the canula; *f* a screw placed upon the cutting instrument, by which we are able to limit the quantity of the instrument which we shall project.

Fig. 13. Is the instrument by which I open a passage into the stricture for the caustic; at its extremity are presented four delicate cutting edges of a conical form; the tube or stem is of silver, and can be bent to any shape, by which we can adapt it to any portion of the canal.

DEPENDENCE OF DREAMS ON BODILY SENSATIONS.

DR. GREGORY relates of himself, that he dreamt he was on the top of Mount Etna, and his feet were much burnt by his near approach to the crater. The dream arose from his having a bottle of hot water to his feet, and he slumbered whilst it was there. He had been reading a short time before, of a journey to the top of that mountain. A French philosopher tried several experiments of this sort; he left his knees uncovered, and he dreamt he was on the outside of a diligence during a cold night. A person having a blister applied to the head, fancied he was scalped by a party of Indians. Should we be seized with cramp in the night, we dream of the tortures of the inquisition. If the rain patter against the windows we hear the sounds of cataracts; should the wind be high, the roar of thunders is in our ears. The Eltrick shepherd, in one of his poems, has given us a dream of terrific misery arising from the effects of thirst. The dreams of hypochondriacs generally arise from real sensation; and when after a full supper the stomach is distended, we fancy some offensive quadruped of immense weight is pressing on our breasts. It is said Mrs. Radcliffe, Dryden, and Fuseli, eat indigestible suppers in order to dream horribly; no one will deny that they succeeded. Opium eaters at first have dreams of transcendent beauty, but when the stomach becomes disordered by the long continued use of the

drug, nothing can exceed the horror and gloominess of their visions. The wonderfully fascinating and strange "Confessions of an English Opium Eater," bears testimony of the truth of this remark.

—o—

British Association for the Advancement of Science.

The sittings of the British Association for the Advancement of Science terminated on Saturday last. It was the general opinion that the meeting was the most successful hitherto held by the Association, and the foreign members spoke in terms of the highest praise of the hospitality with which they were treated. The greatest interest was taken in the proceedings by the respectable inhabitants of Dublin. The numbers of new members admitted was 600.

Annual Report of the Society of Apothecaries.

It appears by this report that during the last year 456 candidates applied for examination, of which 391 were admitted, and 65 remitted to their studies. The Court regret that they have been compelled to reject so large a number, but have felt great gratification at the increased attainments of the applicants generally. The number of medical students in London, 1834-35, was 980, and in the provincial schools 409.

Portrait of Dr. Johnson.

A portrait of Dr. James Johnson has been just published, by Mr. Higley, which is a most faithful likeness, and a beautiful illustration of the art of mezzotint.

Dr. Johnson is universally known as a journalist and an author, and few have done so much for the diffusion of medical knowledge. His literary fame has raised him to the honoured station of Physician to his Majesty, and his great ability and experience have secured him a most extensive private practice. This portrait will be placed by the side of those of other eminent characters.

Quack Testimonials.

We are happy to perceive that Professor Green has applied to the Court of Chancery for an injunction to restrain a Mr. Franks, the proprietor of a "Specific Solution," from publishing a private note, given by Mr. Green, as a testimonial in favour of the efficacy of the above-named nostrum.

We trust that other members of the profession will take a salutary lesson from this proceeding, and be more cautious in future in giving certificates in favour of secret medicines, and certain instruments. It is a disgrace to the profession to see advertisements of this kind headed with the names of our ablest physicians and surgeons.

LECTURES

ON THE

INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXVII.

Transmission of the Stimulus of Volition.

SUCH are some of the principal actions to which sympathy and passion or instinct are the ordinary stimuli, but which volition can, to a greater or less degree, affect or modify; but there are others, on the contrary, which are commonly excited, at least in man, by volition, and only occasionally by sympathy and passion or instinct. Of this nature are those more or less connected with respiration, by which we whistle, whisper, speak, sing, and blow wind instruments; those connected with sensation, by which we regulate the motions of the nostrils, the eye-balls and their appendages, and the external ears, so as to adapt them to their respective functions: and those comprehended more particularly under the head of voluntary motion, by which we bend in any direction, and rotate the head and spine, and by which we effect the several processes, on the one hand, of pushing, pulling, grasping, dividing, striking a blow, constructing works of art, and so forth; and, on the other, of standing, sitting, kneeling, lying, walking, leaping, running, swimming, and numerous others. All those actions, in short, which commonly originate in deliberate design, which are at first generally more or less incompetent to effect the desired end, and which become only progressively perfect, are with propriety referred to this head, since these, as already stated, are the characteristics of a rational as distinguished from an instinctive action (a). Many of these actions, however, become, even in man, occasionally instinctive, as in the case of enthusiasts, or persons under extremely strong excitement, or in whom the influence of reason has been diminished by a certain degree of fatuity or furiosity, provided always such persons have previously possessed reason sufficient to bring these actions to perfection. And, indeed, all these actions become by habit in a certain sense instinctive, the instinct perpetuating the successive improvements which volition has made, till at length volition only determines to the performance of these actions on any given occasion, and sets the requisite muscles in motion, while it is instinct which enables them to act with ease and accuracy. But, in the lower animals, a great number of these actions appear to be always and from the first instinctive. Thus, the process of hoarding up grain by the ant, and honey by the bee, that of depositing their ova, by many of these animals, in appropriate places, that of migrating by several gregarious tribes, and that of constructing its web by the spider, its cocoon by the silk-worm, its comb by the bee, its nest by the bird, and its hut by the beaver—all involve many of the actions above enumerated, but the stimulus by which they are excited is apparently, not volition, but instinct; and such actions are accordingly undertaken by them without any deliberation, conduce, in the most effectual manner, to the end in view, and are as perfectly

(a) Accordingly, in a perfectly drivelling idiot, who has never possessed sufficient talent to attain this perfection, the speech is commonly harsh and inarticulate, the eye-balls have not the degree of convergence requisite to single vision, or there is a decided squint, and the motions of the head, trunk,

and limbs are awkward and ungainly in the extreme. This furnishes sufficient evidence that all these actions are in man naturally rational and not instinctive, for all the latter actions are in general as accurately performed, by a confirmed idiot, as by other persons.

performed, the first time they are undertaken, as at any subsequent period. It would be, nevertheless, as great a mistake to believe that *all* the actions of the lower animals are instinctive, as that all those of man are rational. The ant hoards its grain as actuated by instinct; but it is as actuated by reason that it bites off the germinating part of it, if such grain have ever sprouted on its hands—it is from instinct that the spider constructs its web; but it is from reason that it chooses its time for pouncing on the prey which this web has entangled, and refrains from doing so whenever it perceives at hand an enemy to be dreaded—it is instinct which prompts the bird to build her nest; but it is reason which prompts her to choose a more secure place for doing so, if she have ever had her eggs stolen. All the former actions are impetuous, immutable, and perfect from the first—all the latter are deliberate, adapted to the occasion, and improvable by practice. It requires no experience to excel in instinctive actions; but it is experience alone which renders a cat wary and successful in secreting her kittens, or a hare or deer in eluding the arts of the huntsman; and the tricks of an old fox, both in attaining his prey, and in avoiding the snares spread for him, are so remarkable, that the term has become emblematical of a cunning fellow. Any animal which is educatable—if the expression may be allowed—is in the same degree rational; and that many of the actions of the lower animals are improvable by education, natural or artificial, is as certain as that many of those of man are not so. The actions of both have obviously a double origin; and the only difference between the two appears to be that, while the greater number of the actions of man spring in general from reason, and comparatively few from instinct, in the inferior tribes of animals the majority are instinctive, and few only in comparison are rational. Hence, while some of the analogous actions of both are excited in both by instinct, and others in both by reason, there are not a few of these analogous actions which have in man, as elsewhere observed, a very different origin from what they have in brutes. The fabric which man brings to comparative perfection only after long reflection and repeated failures, and profiting, not only by his own experience, but by that of the myriads who have gone before him, the insect, the bird, or the quadruped undertakes without deliberation, and brings to perfection, not only in its own generation, but the first time it is attempted—the sounds which man acquires the power of uttering only after months and years of observation, and fruitless efforts at imitation, the bird or the quadruped emits from the instant that its organs are sufficiently developed for the purpose, and would have done so equally well had it never heard a similar sound before. Man does these things by reason—the brute by instinct. Man is, in these respects, a free agent, and revels in his freedom, attempting much, and this infinitely diversified, but as often failing as succeeding in his attempts, and never arriving at absolute perfection in their results—the brute is in these respects a blind machine, engaging in little, and this always the same, but in its operations infallible, and in their results absolutely perfect. With respect, indeed, to the actions exercised by every form of matter, man or brute, organized or inorganic, it appears that such actions are, for the most part, more precisely adapted to the end in view, and their results more admirable, the further removed is the power by which they are severally excited from reason and volition, as exercised by the immediate instruments of these actions, and consequently the more these instruments act in blind obedience to immutable laws imposed upon them by the Creator. What action, sensible or molecular, of organized beings, can compare in accuracy of movement or harmony, and beauty of results, with the revolutions of the planets on the one hand, or the crystallization of a mineral on the other? the only power engaged in which is that of attracting and repelling; what action of the latter, excited by sympathy and passion, or instinct, can compare, in these respects, with the contractions of the heart, or the process by which the flower of the humblest plant, or the eye or ear of the lowest animal is constructed? the only or chief power engaged in which are certain direct stimuli distinct from either; and what action, lastly, excited by volition, can compare in these respects with the motions of the chest in respiration, or the formation, by the lower animals, of any of their natural fabrics? the only power engaged in which is sympathy and passion, or instinct? The most precise actions excited by volition—at any rate before such actions have become partially instinctive by habit—are but bungling imitations of the least accurate of them, and give rise—at any rate before they have been improved by long and patient cultivation—in comparison with the least admirable results of the latter, to rude and coarse performances. The being thus exercising volition is, perhaps, morally exalted in proportion as he becomes a free agent; but such volition, in its physical operations, is but a poor substitute for the powers which it affects to supersede.

Volition, as a stimulus to irritability, is not only much less extensive in its operation than sympathy and passion, or instinct, but this operation is much less constant. If life and irritation are almost synonymous terms, and if the irritation of each part of the body, at least in the higher tribes of animals, exerts by sympathy a more or less powerful influence over all the rest, it is obvious that during life this power can never be quiescent; and if the irritation of other organs be thus continually extended to the rest by sympathy, there is good reason to believe that the action of the brain is equally constantly—at least during

the waking hours—extended to the rest by passion and instinct—not indeed in any very sensible form, but uniformly and equally. But such does not appear to be the case with volition, its exercise as a stimulus to irritability taking place apparently at irregular intervals only. And it is in this way that we may perhaps explain the origin of the common error, that the so called voluntary muscles are alone liable to fatigue. All the muscles of the body, whether involuntary or voluntary, are perhaps equally liable to fatigue, provided their irritability be stimulated to a greater degree, or for a longer time than natural; but while this is never the case, at least under ordinary circumstances, with the former, the stimulus of volition acting upon the latter is always in some degree a preternatural one, and the action so induced is consequently sooner or later succeeded by exhaustion. Nor is it true, as is sometimes added to increase the marvel of the thing, that the involuntary muscles are capable of sustaining, generally speaking, a much more permanent action than the voluntary. It is common to contrast the heart, as continuing in constant action during a long life, with the muscles of the trunk and extremities, as enjoying a great deal of repose; but it is probable that the sum of repose enjoyed by the heart is, in fact, as great, or greater, than that enjoyed by many of the muscles last alluded to. For we must keep in view, that the heart is two muscles, and not only one, the auricles acting at one time, and the ventricles at another; and this circumstance, in addition to the short repose of the whole heart during each series of actions constituting its rhythm, reduces the proportion of each twenty-four hours occupied by the actual contractions of the auricles to about six, and that by the ventricles to about twelve, whereas that occupied by the contractions of many of the muscles of the trunk—of those which keep the head erect for example—is not, in general, less than sixteen, that is to say, the whole time the person is otherwise than in the recumbent posture. Nevertheless, it is not probably as determined by the relative duration of the contractions of the voluntary muscles, that they become so frequently affected with fatigue, while the involuntary muscles do not, but from the contractions of the former, as just observed, being always more or less a forced state, the stimulus of volition being, as it were, accidental and adventitious in its operation; but to this subject further allusion will be made in future.

With respect to the channel by which the direct and primary action of the brain, in which volition consists, is translated to distant parts, so as to act on them as a stimulus to their irritability, there is not the same controversy as with respect to sympathy and passion, or instinct, regarded in this capacity—it is pretty certainly the system of nerves called the proper motiferous, and the motiferous portions of those called regular, in conjunction with such of the respiratory nerves as are furnished also with motiferous filaments—but, previously to adducing the principal proofs of this fact, it is proper to say a few words respecting a peculiarity in the operation of volition in this way, as distinguishing it from that of the other indirect stimuli just mentioned. The peculiarity alluded to consists in this, that, whereas in the latter case, the direct irritation of any other organ, or the direct action of the brain is the immediate means, through the nerves, of exciting that indirect irritation constituting the obvious phenomena, in the former, the direct action of the brain appears to involve first, an intermediate action of another part of the nervous system, and it is this intermediate action which is the immediate means, as translated by the nerves, of exciting that in which voluntary motion consists. It may appear at first sight, that this is a very unnecessary addition to the complexity of a process already by no means simple; but numerous considerations seem abundantly to justify, and even to require it. Thus, in the first place, it will be evident upon reflection that volition, which implies a distinct consciousness, on the part of the being exercising it, of the end in view, is never exercised with respect immediately to any of the muscles, such muscles being excited to action, not by their possessor willing that they should act, but by his willing to effect certain movements, which movements require the action of such muscles. A man never wills, for example, that the flexor muscles of his finger should contract—he wills merely to bend his finger, and these muscles—of the very existence of which he is most probably quite ignorant—act in consequence. It is not the *muscles* then, but the *movements*, which are in any case voluntary, since it is absurd to represent any power as exerting a deliberate influence over organs altogether unthought of or unknown. It is a very different thing with respect to passion or instinct, which, whether it conduce or not to a definite end, does not imply any consciousness of that end on the part of the being exercising it, and which, therefore, may be presumed to extend its influence immediately to the muscles—however ignorant this being may be of their existence—the resulting movements being altogether unanticipated and uncared for. Both volition and passion or instinct consist in certain actions of the brain extended to other organs; but while the latter, which is without deliberate design, is transmitted immediately to the muscles to be acted on, the former, which implies such design, cannot be presumed to be so; and if it be not the action of the brain which, in this case, is so translated to the muscles, it must be that of some other part immediately connected with the brain, and involved in this particular action of that organ, but the action of which is, like that of the brain itself, in the case of passion or instinct, without any consciousness of an end in view. Again, volition, implying, as it does, a distinct consciousness of one end, cannot easily be conceived capable of exerting a simultaneous ope-

ration upon so many different muscles, as are often called into action in effecting even the simplest movement; and perhaps the totally different movements of the right hand and the left, as manifested in playing on a musical instrument, imply two general seats of action more decidedly distinct from each other, than that of mere volition can be presumed to be. And what shall we say of the seat of the power which actuates the three hundred muscles, calculated to be simultaneously in action when, like David before the Ark of the Lord, a person is dancing, singing, and playing on the harp all at the same time? Further, there is reason to believe, that volition is not only incapable of a simultaneous operation on several muscles, but that it is not in constant operation during any continued exercise of voluntary motion, such as takes place in playing a piece of music with which one is familiar, or even in continued walking; in effecting which, volition, or the primary irritation of the brain, appears to be instrumental only in setting off these motions, as it were, while it is by that of some other organ that they are perpetuated, the requisite celerity and precision in the motions of the muscles having been already acquired by habit, and having become therefore instinctive. We know, at least, that the thoughts are often constantly and intently engaged in other things, while such movements are going on without the least interruption. Another argument in favour of the presumption that, when volition acts in effecting the voluntary movements, it is only through some intermediate action, is the fact, that the most powerful act of volition is quite inert in exciting these movements when this intermediate action does not take place, whereas, without any act of volition, they are so excited by the spontaneous occurrence of such action. Of the former of these phenomena we have examples in palsy of voluntary motions alone in incubus, or common night-mare, and in trance, in which, however energetic may be the will to effect certain movements, the power of doing so is quite lost; of the latter, in palsy of sensation alone, combined with cerebral apoplexy, in somnambulism and in walking catalepsy, in which, without any volition, the movements of the so called voluntary muscles are as perfect as when consciousness is entire. Nay, it has been established by observation and experiment, as will be stated more fully presently, that the communication between the brain—the seat of volition—and the immediate source of the nerves going to the voluntary muscles may be entirely intercepted, and still these muscles be exerted to action. Nor is it only without the will, but even against the will, that the contractions of the muscles, which are usually called into action by volition alone, are frequently excited; as occurs in tetanus, epilepsy, hysteria, chorea, and all the spasmodic and convulsive diseases which are confined to muscles appertaining to the proper animal functions. It may appear indeed, that, if this be admitted as an argument in favour of the doctrine under consideration, the occurrence of angina pectoris and pertussis, of palpitation of the heart, of gastrodynia, colic, hydrophobia, and so forth, which consist of spasmodic or convulsive affections of muscles commonly excited, among many other causes, by sympathy, might with equal propriety be cited to prove that sympathy acted on such muscles, not immediately, but through the medium of a new irritation, which might take place sometimes independently of sympathy. This, however, is not the case; for while it is always from excess of either sympathy, or some other stimulus to which these involuntary muscles are naturally subservient, that these latter diseases arise, it is never by excess of volition, which is the only stimulus that the voluntary muscles, in an indirect manner, exclusively obey, that the former diseases, distinctly confined as they are to these voluntary muscles, are excited. It is clear, then, that volition is, under ordinary circumstances, only the first link in a chain consisting of three such links, since under extraordinary circumstances there still remain the two necessary to every instance of indirect and secondary irritation, which two are capable of acting, not only without the aid of the first, but even in opposition to its influence. Lastly, if the action of the brain in which volition consists operated, like that constituting passion or instinct, on the irritability of the muscles without any intermediate action, we should expect that the brain would be found to be large in all animals in proportion to the force and energy, as well of their voluntary movements and sensations, as of their instinctive movements and mental operations; whereas it is sufficiently well known that, while this correspondence is pretty well observed with respect to the two latter, this is so far from being the case with respect to the two former, that the size of the brain is within certain limits rather inversely, than directly as the force and energy of the voluntary motions and sensations, as will sufficiently appear by contrasting, in these respects, almost any one of the lower animals with man.

If, then, there be this intermediate action in every case of voluntary motion, the next question that arises is, what is the seat of it? And the answer may be tolerably decided—that it is the anterior columns of the spinal cord, whence all the nerves ministering to the motions of the reputedly voluntary muscles directly arise. This presumption, while it is quite compatible with all the facts which have just been enumerated as militating against the doctrine that it is by the immediate translation of the stimulus of volition to the muscles to be acted on, seems to be borne out by direct observation and experiment. It has been shown, as lately stated, not only by numerous cases in which a separation has occurred, from either monstrosity or disease, between the brain—the seat of volition—and the

spinal cord, or between the upper and lower portions of the latter, but also by experiments in which this connexion between the brain and either the whole or a part of the spinal cord has been artificially cut off, that the motions of the muscles supplied by nerves coming from the part of the cord below the division, which motions are naturally excited by volition, were not materially impaired, the mere action of this part excited by other means, as happens in palsy of sensation alone combined with cerebral apoplexy, in somnambulism and walking catalepsy, being still competent to produce them (*a*). And it seems hence fair to infer that as in palsy, voluntary motion alone, and in incubus, the brain and posterior columns of the spinal cord are still in action, while the anterior columns are not so, and in trance the brain without either the posterior or anterior columns, so in the former case with that of the posterior columns of the spinal cord also, but in the latter without it, in the diseases just mentioned the action of the brain is suspended, while that of the anterior columns is still maintained; and this theory is the more plausible from the circumstance that tetanus and the other spasmodic and convulsive diseases of the so-called voluntary muscles pretty certainly depend on a morbid action of this part. Further, it is quite impossible to explain why the two anterior pillars of the spinal cord should consist of grey, as well as white matter, which is not the case with the two lateral pillars, unless it be conceded that the two former are not only the channels of a power, but the seat of the action in which this power immediately consists, whereas the two latter serve only to communicate a power generated elsewhere. It has been already presumed, in speaking of the office of the ganglionic system of nerves, that the grey matter of the nervous tissue is always the source of that particular property or power which distinguishes each department of the nervous apparatus, while the white matter may be regarded as only a kind of conduits, by which this property or power is, as it were, disseminated, not indeed *per se*, but by virtue of some molecular change effected in the matter in question (*b*); and, if this be

(*a*) One case of this kind is related in the *Journal de Physiologie* for 1823, in which the power of moving the voluntary muscles, as well as the faculty of sensibility, was unimpaired in a man between the upper and lower portions of whose spinal cord there was an almost total want of continuity for six or seven inches; and some analogous cases have been since recorded. The same negative result of artificial division of the spinal cord in the lower animals was noticed long ago by Redi and Swammerdam; and it is expressly stated by Dr. Wilson Philip, as the conclusion to be drawn from his experiments, that "the division of the spinal marrow does not destroy any of the functions of either half of it, the palsy of the lower part of the body, occasioned by its division, arising from that part having its communication with the principal source of sensorial power (i. e. the seat of volition) destroyed." (*On the Vital Functions*, 1817). It is observed, likewise, by Mr. Mayo, that if the spinal cord be divided in a rabbit in the centre of the back, the hind leg still retains both the power of motion and the faculty of sensibility; (*Outlines of Physiology*, 1829); so that we must believe that the "palsy" which a few pages onwards he describes as "the uniform result" of such a division, relates only, in as far as voluntary motion is concerned, to the interception of volition. Volition may be entire, and the intermediate action which should directly excite the voluntary movements may likewise be entire, but the former does not give rise to the latter.

(*b*) An indefinite sort of surmise that the grey matter of the nervous tissue is analogous to the secreting part of a gland, as the white matter is to the ducts of such

gland, appears to have been from the earliest times entertained. Thus by Hippocrates the brain has been described as *ὡσπερ καὶ αἰετες*, while by Praxagoras the nerves were represented as performing the office of ducts; and similar notions were inculcated by Harvey, Spigel, Bartholin, and others; but it was Malpighi who attempted for the first time to demonstrate, by means of long boiling, and with the help of the microscope, the glandular structure of the grey matter of the nervous tissue, and the fibrous structure of the white, and to prove that the latter was to the early point of the former "veluti proprium vas," for the conveyance of whatever it was pleased to furnish. In these speculations Malpighi was supported by Willis, Malacarne, Vieussens, Wepfer, Bohn, Leeuwenhoek, and many others, almost down to our own times; and although the grey matter of the nervous tissue certainly does not, like truly glandular structure, secrete any thing substantial, whether "an exquisitely fine and active fluid," in the character of "nervous energy," or a proper "succus nervosus" indirectly ministering to such nervous energy, the comparison is nevertheless an impressive and instructive one. By Gall and Spurzheim the grey matter of the nervous tissue is represented rather unhappily as the matrix of the white—a position which has been since combated by Tiedemann, who has shown that in the embryo the formation of the white matter long precedes that of the grey. It is remarkable, however, that this observation is so far from controverting, that it very strongly corroborates the notion of a kind of analogy between the grey and white portions of the nervous tissue and the parenchymatous and tubular parts of a gland,

the case, as every view of the matter seems to testify, it will follow that the possession by the anterior columns of the spinal cord of grey matter is a strong collateral argument in favour of the doctrine that volition operates in exciting the action of the voluntary muscles, not directly, but only through the medium of a new power consisting in a proper simultaneous action of this part. It must not be omitted to notice, lastly, that the size of the spinal cord, taken collectively as compared with that of the brain, is, in almost all classes of animals, great in proportion to the form and energy of their voluntary motions and sensations, as compared with that of their instinctive motions and mental operations; the relative size of the spinal cord of fishes and reptiles in general being as about 1 to 2, that of birds as 1 to 3, that of quadrupeds as 1 to 4, that of the male of the human species as 1 to 24, and that of the female as 1 to 25 or 26. It is worthy of remark, likewise, that if this doctrine be admitted—that the anterior columns of the spinal cord are the seat of the intermediate stimulus to voluntary motion, which stimulus, as it is excited by that primary action of the brain in which volition as a mode of thought consists, gives rise to an irritation of a part at a distance—a very beautiful reflex analogy is maintained between this stimulus to voluntary motion and sensation, which in like manner has its seat, as will be seen in future, in the posterior columns of the spinal cord, and as it is excited by some irritation at a distance, so it gives rise to some mode of thought. Two journeys, as it were, in opposite directions, seem to be taken in the two processes; but in both the spinal cord appears to be not merely a channel of conveyance between the brain and the distant organ, but a very important means of modifying the thing conveyed (a).

the tubular part of the latter being now well known long to precede the parenchymatous part in the date of its development.

(a) Some very vague notions have been from the earliest ages afloat respecting the instrumentality of certain portions of the brain in immediately effecting voluntary motion. By Galen, as the sensiferous nerves were represented as arising from the cerebrum, so the motiferous were described as arising from the cerebellum; and the doctrine that the cerebellum therefore was immediately subservient to this process continued in vogue till the time of Willis, who, followed by Vieussens, Boerhaave, Du Hamel, and others, chose to regard the cerebrum as the immediate source of the voluntary, and the cerebellum that of the involuntary motions. Respecting the involuntary motions, however, the question has been despatched elsewhere. In more modern times, Foville, Pinel-Grandchamps, Dugès, Louston, and others, have followed Willis, in as far as they regard the cerebrum as the immediate source of voluntary motion, considering the cerebellum, on the other hand, as the source of sensation; whereas Rolando and Flourens have returned in some measure to the hypothesis of Galen, placing sensation in the cerebrum, and representing the cerebellum not perhaps as the immediate source of voluntary motion—which the latter indeed expressly refers to the corpora quadrigemina and spinal cord—but as its regulator. Among the arguments adduced in favour of regarding the cerebrum as the immediate source of voluntary motion—to say nothing of the circumstance of its direct continuity with the anterior columns of the spinal cord, whence all the nerves which minister to voluntary motion immediately arise, which is of course in favour of regarding this latter organ in that capacity—may be mentioned the facts, that a general disease of one side of the cere-

brum usually paralyzes all the voluntary muscles on the opposite side of the body—the fact of its being on the opposite side being explicable from the decussation of the fibres which takes place between the cerebrum and anterior columns of the spinal cord on a line with the corpora pyramidalia; and that a local disease of certain parts of the cerebrum, for example the thalami optici or corpora striata, paralyzes particular voluntary muscles, such as, in the former case, those chiefly of the upper, and, in the latter, those chiefly of the lower limbs. It is further remarkable that a section of one thalamus opticus or one corpus striatum appears so to act on the voluntary muscles as to cause an animal to revolve incessantly towards the injured side, while a section of both seems to have the effect of causing it to move constantly forwards. On the other hand, it has been alleged in favour of regarding the cerebellum as the immediate source of voluntary motion, that although it is less directly continuous with the anterior columns of the spinal cord than the cerebrum, yet a general disease of one side of the cerebellum as commonly paralyzes all the voluntary muscles on the same side of the body as such a disease of the cerebrum does those on the opposite side—there being between the cerebellum and spinal cord no such decussation of fibres as takes place between the cerebrum and the latter organ; that local disease of the cerebellum produces on particular voluntary muscles effects similar to those resulting from such diseases of certain parts of the cerebrum; and that as a section of certain parts of the latter seems to cause an animal either to revolve towards the injured side, or to move forwards, so a section of one of the crura of the cerebellum, or the removal vertically of a large portion of one of its hemispheres, appears to give rise to the former effect—the motion being instantly

LECTURE XI.

*Inflammation of the Buccal and Pharyngo-
Laryngean Regions—Gingivitis—Aphthæ—
Quinsy—Angina—Gangrenous Sore Throat
—Diphtheritis—Croup, &c.*

To form an idea of the importance of the

buccal and pharyngo-laryngean inflammations, you need only reflect on the organs in which they are seated, and their connexion with many of the principal nuclei of life. The velum palati, where they are frequently observed, is in close connexion with the stomach, as you may certify by producing vomiting by tickling the uvula. Nor are the sympathies of the larynx with the respiratory apparatus less evident, since cough is ordinarily produced by irritation of the glottis; there it is that we have the sensation of coughing, just as in the nose we experience sneezing. The pharynx also is in strict relation with the stomach: so soon

stopped by injuring the other side of the organ in a similar way—while the removal horizontally of a large portion of both hemispheres seems to cause an animal to move constantly, not forwards, but backwards. It appears, accordingly, that the arguments are almost equally valid, or rather equally destitute of validity, for regarding either the cerebrum or the cerebellum as the immediate source or regulator of the voluntary motions, some of them even going to prove, as observed by Magendie, that these organs are useful, not so much in moving the body as in keeping it still. With respect to the general or local diseases of the brain, followed by palsy of the voluntary muscles, unless such diseases involve also the anterior columns of the spinal cord—as is very frequently the case—they take effect probably more or less extensively only as far as they intercept volition; and with respect to the various local lesions of the brain followed by such singular effects, they prove only that the voluntary motions may be affected through the brain, not that they immediately depend upon this organ. Indeed, if this argument in favour of the doctrine in question be allowed, we must conclude that the brain is the immediate source or regulator, not only of the voluntary, but of the involuntary motions also—of that of the heart, for example, which is so easily influenced by the state of this organ. The perturbations of the brain may disturb the actions of either the voluntary or involuntary muscles—and it was indeed found, by Dr. Wilson Philip, that such perturbations produced very similar effects on both (Phil. Trans. 1815); but that organ is surely not to be regarded as the immediate source or regulator of the motions of another, which only requires of it not to interfere. And even admitting that the effects of actual physical lesions of the brain are more remarkable on the voluntary than on the involuntary muscles, is not this fact easily explicable, when we reflect on the intimate structural union between this organ and that which really is in all probability the immediate source of voluntary motion? so that while the involuntary motions are involved only sympathetically in such lesions, the

voluntary are so, not only sympathetically, but directly also. Hence we find that the nearer such lesions approach the point of union—in other words, the nearer they are to the base of the brain—the more striking these effects become. It is not improbable, also, that some of these effects may depend, not upon any direct influence exercised by the brain as the immediate source of voluntary motion, but upon mere volition, exerted in consequence of the lesions above alluded to. Thus, a section of one thalamus opticus, of one corpus striatum, or of one of the crura of the cerebellum, or a removal in the vertical direction of a large portion of one of the hemispheres of the latter, in all likelihood produces a kind of vertigo, in which the animal fancies itself forcibly urged in a direction contrary to that in which it is found to revolve, and this revolving motion is excited by the will, for the purpose of counteracting this supposed power; and in the same manner probably a section of both thalami optici, or of both corpora striata on the one hand, or a removal in the horizontal direction of a large portion of both hemispheres of the cerebellum on the other, gives rise to an impression of being violently propelled respectively backwards or forwards, and the animal voluntarily moves forwards or backwards in order to resist this imaginary impulse. A wonderful case, related by Dr. Watt (Medico-Chir. Trans. 1814), and another by Mr. Mayo (Outlines of Physiology, 1829), in which, among other singular notions, this revolving motion was more or less constantly maintained, and the Forfarshire louping ague, as it is called (Edinb. Med. and Surg. Journ. 1807), manifesting itself principally in an uncontrollable propensity at times to run straight forwards, afford beautiful illustrations of the influence of certain morbid affections of the brain upon the voluntary motions, but no more justify us in believing that it is the immediate source of such voluntary motion, than the alterations which the hand sometimes makes in the movements of a watch would justify us in the belief that it is by this hand, and not by its own spring, that such movements are immediately effected.

as one is out of order the other is diseased, and irritation is conveyed both from the pharynx to the stomach, and from the stomach to the pharynx. Add to this, that these parts are provided with lymphatic and blood-vessels, nerves, and nervous papillæ, a cellular tissue in some degree erectile, and multiplied mucous follicles. The amygdalæ possess an areolar tissue and a congeries of follicles, whose orifices open on the lacunæ of the mucous membrane. Between the two mucous folds of the velum palati there are exceedingly active muscles. All these parts are liable, even in the normal state, to numerous and sometimes violent movements from the stimulus of instinct, that is to say, from the stimulation of the viscera re-acting under the influence of certain parts of the cerebro-spinal nervous system.

You may therefore well imagine that inflammations of these parts cannot proceed in an absolute manner, and independently of the viscera; a similar relation was advanced with regard to those of the eye. Thus, that derangement of functions, that disorder of secretions, those convulsions of a certain number of organs, that obtain in irritations, commence in a more immediate and speedy manner. Thus too the inflammations of the various organs succeed and become connected with each other with greater rapidity. In these inflammations we have a preliminary instance to the consideration of others more complicated, of others wherein the deduction from the causes, from the symptoms, the mode of suffering, the progress, termination, &c. is more difficult, because the facts are multiplied, and frequently are apparently contradictory. Here a renewed and increased attention becomes necessary, in order to arrive at clear deductions; but as all minds are not equally capable of this, you will see them fix upon different ideas—ideas agreeable to the calibre of each mind; nor ought you to wonder at the discrepant opinions we meet with. Such necessarily arise whenever the elementary bases of a judgment or conviction become more complicated. In order to prevent them, as much as may be, from arising among you, I shall first of all present the simple facts to you that more particularly refer to surgery, and which require mechanical means. In this manner I shall continue, as I have hitherto done, to initiate you by the surest mode into the science of inflammations, at the same time that you will be made readily to comprehend how those, of which we proceed to speak, have become objects of so much controversy. You can then by yourselves, if you choose, try the balance, and find where reason is, and where passion.

Inflammation may appear in different forms in the parts above mentioned. It may be purely inflammatory, and so violent as to suppress all secretion, and leave only a red surface—a fact that obtains in other secretory organs, which are liable to shades

of irritation in which nothing but a sanguineous injection is observable; such a state is even seen in the skin. I lately shewed my pupils, at Val-de-Grâce, a case of scarlatina in which the skin was as red as blood; I told them I had seen even a worse case than that, a case in which not only the skin, but the subcutaneous cellular tissue, was transformed into a sanguineous tissue. You know very well that there are pneumoniæ of a purely sanguineous character. You may therefore well imagine the shade in question; it is sanguineous inflammation par excellence, and the highest degree of bucco-pharyngo-laryngean inflammations; with this we will commence. We shall then proceed to those that are less sanguineous, and end with those of a contrary character, and on which it is difficult to form a judgment—*judicium difficile*, as Hippocrates has it.

This shade tending to sanguineous inundation, is exhibited in a double form, one purely membranous, the other phlegmonous; the latter is not likely to take place every where, but is frequently observed in the tonsils and soft palate. In the latter it may be smooth, with considerable sanguineous turgescence, not only of the palate, but of the pharynx and larynx also, without any appearance of mucous secretion.

Next come some lower shades accompanied with exudation: these are numerous, and have given rise to as many different opinions. First there is the purely catarrhal shade, and of this that belonging to the common cold is the least intense; in fact, cold may produce mucous secretions in the soft palate, the tonsils, and even in the pharynx, but more commonly in the larynx and trachea. After this comes another shade approximating to the last named, in which a secretion really exists, but ordinarily of a dense, firm, coriaceous kind, and sometimes edged in by an inflammatory swelling, so as to present a depression resembling an ulceration. It may be entirely seen in the tonsils, imperfectly so in the pharynx, and is not completely ascertained until after death. Shades next appear in which the mucous secretion is less dense and coherent; these are more readily propagated than the preceding, invade the parts rapidly, and go beyond them, being seen to descend into the œsophagus, stomach, trachea, and bronchi.

In another instance the inflammation may be confined to the gums and internal cheeks, and be there exhibited in an exceedingly phlegmonous, non-secretory, and red form. In such state I have both seen and had it combined with a cerebral congestion, just as the purely inflammatory coryza spoken of is. In these parts too it presents itself with an exudation of white mucosities which coagulate and resemble clotted milk; this is the aphthous form in which the entire of the gums is red and covered with small excoriations. The secreted matter may be

tenacious and edged in on some points so as to resemble an ulcer; and on falling off it occasionally leaves an actual ulceration. In some instances it predominates on the edges of the gums, and is more or less inflammatory; still there is always a white and mucous exudation.

Besides these forms, some specific ones exist, such as the scarlet inflammation, the syphilitic and mercurial inflammations; these however we defer to the time and place when we speak of the specific phlegmasiæ which will follow the common ones; with these latter a comparison of them will be made.

The causes of these forms of inflammation are not easily ascertained, and require both time and close observation. Those of the simple and purely inflammatory buccal and pharyngo-laryngean phlegmasiæ are recognized by every one, because, as the question is confined to one or two elements, the deduction is easy, and for the same reason identical. Indeed it appears very clear that young and adult persons, living under the influence of a full and stimulating diet, may contract these—and especially the phlegmonous—inflammations, under which are ranged those called anginæ and quinsies, whenever they are exposed to cold or heat; for they are apt to appear in hot as well as cold weather, though perhaps not so frequently, in consequence of the preservative excretory action of the skin. The causes of such inflammatory consequences then admit of no doubt.

Disputes have arisen more particularly about those shades of inflammation in which there is an exudation, and this because they originate in more complex circumstances than the preceding ones, while at the same time all intellects are not equally capable of appreciating these circumstances. The shades in question are observed in children as well as adults, in the robust as well as the weak. Among the latter, such as children, women, and lymphatic subjects, they exhibit a series of degrees that renders their forms infinitely more diversified than in other conditions of age, sex, or temperament. But no such disputes exist with regard to catarrhal inflammations; when, consequent on cold, pain of the throat, hoarseness, some tumefaction and thick mucus are observed, there is no difficulty in asserting that the whole is the product of cold—it is a cold. Still a predisposition must be admitted: for should cold impress on one with an inflammatory disposition, it may produce, instead of a simple catarrhal exudation on the velum palati or pharynx, a most intense inflammation, and one of a more or less phlegmonous character. Each one has his own mode of being sick—a truth not properly comprehended, though so frequently repeated; if it were, how should we see such frequent creations of particular diseases.

When inflammation of the throat is fibrin-

nous, the pellicle dense, adherent to the gullet, visible in one part, in another not visible, there are controversies about its cause. Several authors rather laying stress on the manner in which the disease marches, than on the individual and atmospheric conditions in which it is developed, look upon it as of a most serious kind, and struck with the putrid odour of the mouth, the prostration of the powers, and the danger of suffocation, call it putrid; on the strength of this term they have gone about seeking for extraordinary causes. In other instances the inflammation having failed to produce a fibrous coat so dense, so difficult to detach, and so readily reproduced, but at the same time exhibiting an inflammatory character of a most determined obstinacy, with an ambulatory tendency and propagative disposition towards the respiratory, and even the digestive organs, and they having fixed their attention to the great alterations of the system, and the vast number of fatal terminations—doing this, they have looked upon it as the effect of some hidden condition of the atmosphere, and given it the name of malignant. Both these forms have been referred to gangrenous inflammation; nay, even the most inflammatory affections of the arch of the palate and of the larynx, have sometimes received the qualifications of gangrenous and malignant, when they are developed with great intensity. Generally speaking, whenever great danger and intensity attends a disease, people are not content with the causes that fall under the cognizance of the senses, but go out of their way to seek extraordinary and supernatural ones.

Regarding inflammations of the gums; as, in scurvy, these parts are often inflamed, inasmuch as the same cause that produces it may likewise produce stomatitis and gingivitis, and as inflammations of the same organ resemble each other fundamentally, they have been termed scorbutic even when it was easy to prove that they originated under the influence of cold or of heat, and that no constitutional tendency to scurvy existed. Indeed the latter does not only consist in a red or brown, bleeding, and more or less inflammatory congestion of the gums, but also in a certain number of other lesions that do not necessarily accompany the inflammation in question. This distinction, however, has not been made, and inflammation of the gums has almost invariably been considered as an index of scurvy and treated accordingly. When my colleague and myself arrived at Val-de-Grâce in 1814 and 1815, so dominant was this idea, that the whole of the court-yard was planted with antiscorbutic vegetables, from which tinctures and syrups were prepared, and used to stimulate the gums of the soldiers that were considered in a scorbutic state. But since we began to treat with antiphlogistics those apparently scorbutic inflammations of the mouth that break out in barracks, the sorrowful looking

plants have disappeared, and flowers now occupy their places; this is a change which, like many others, may be considered as a step in civilization.

Aphthæ that are red, spread out over the mouth, and marked with small white spots resembling minute clots of milk, evidently are referable to moist cold acting on a peculiar predisposition; and, so much is this the case, that they are prevented and cured by avoiding that cause, and taking care not to stimulate the mouth.

But the etiology of buccal and laryngo-pharyngean inflammations, as I have laid it down, is contested. More particular stress has been laid on those sorts of epidemics in which the inflammation is supersecretory and propagative; and as these appear in a great number of individuals at once, they have been said to depend on something more than the alternations of heat and cold, and some inexplicable cause, a *quid divinum*, has been supposed to produce them. Moreover, sections of them have been made, and one form only, the propagative, with non-adhesion of the fibrinous coat, has been said to be owing to an extraordinary cause, and this form, which attacks the respiratory and digestive passages, has also been said to be analogous to the gangrenous sore throat of the ancients, and of Aretæus in particular. The frightful ravages formerly made by this inflammation have been cited, and truly it was a depopulating scourge when badly treated, and at a time when science was still in a barbarous condition; it is not the only disease to which terror has given an extraordinary renown. Yet though these ideas and opinions seem to have disappeared in our times, they have nevertheless been raked up in order to maintain that the phlegmasia in question is not a shade of that with which we are well acquainted; a particular cause has been assigned to this phlegmasia, which, not being arrested in the very commencement, is propagated until it produces suffocation and death; and as, whenever there is a mucous inflammation with supersecretion, a horrible fetor prevails in the part, the chorus of the ancients has been joined in qualifying it with the name of malignant, and upholding it, when it prevails, as a *quid corruptum* pervading all nature—an error on a par with that committed with regard to gastro-enteritis, and against which I protested, I am proud to say, triumphantly, spite of the forced silence to which I was condemned by circumstances for many long years.

These diseases have likewise been said to be contagious and communicable by respiration, and experiments have been cited that indeed appear convincing that the thing may sometimes happen. But it has been maintained that the angina with easily detached mucous supersecretion—which corresponds to the gangrenous sore throat of the ancients, and now-a-days has the name of *diphtheritis*—is contracted in innumerable circum-

stances by inhaling the breath of those attacked with it; this is at least an exaggeration, for day by day medical attendants open the mouths of patients so affected, for the purpose of examining the throat, and go away without contracting diphtheritis. So also of that species of gastro-enteritis called typhus, which is likewise sometimes communicated. All this however is conceivable; at times and in places when individuals who appear to have contracted it by contagion are affected, causes exist, such as atmospheric vicissitudes, that act upon all individuals, modify those who are predisposed—young and lymphatic subjects for instance—and dispose them to contract the disease whenever any slight stimulation is added to the existing causes. This is no contagion, but an actual inflammation developing itself in consequence of a particular predisposition. For the rest this fact is not exclusively peculiar to typhus and gangrenous sore throat, but is observable in all the mucous phlegmasiæ. In fact there is not one of them, from urethritis to gastro-enteritis and dysentery, of which instances of contagion are not quoted; but what do these instances prove? that individuals predisposed and placed in the conditions in which these diseases rage epidemically, are attacked simultaneously with others, or sometimes in consequence of others. It is even possible that the halitus of a phlogosed mucous surface may inflame another mucous surface; but these are not cases of independant and absolute contagions like that of small-pox. To shew their actual existence, the disease constituting the epidemic, and which is thought to be communicated, should always resemble itself; now such is not the case; on the contrary, whenever small-pox is transmitted, it is because it is exactly reproduced in the individual that receives it—small-pox is always small-pox. True there are more or fewer inflammatory symptoms in the viscera, more or less rapidity in the progress of that disease, more or less danger, &c.; but the essential, fundamental, invariable character, the pustules, is never wanting. Such is not the fact in diphtheritis. Read M. Bretonneau's work and the authors he cites, and you will see an immense variety of epidemics, of histories of angina with tenacious concretion, commencing in the throat and velum palati; instances of croup, of intense phlegmasiæ beginning and ending in the larynx, while others were propagated; cases of gangrenous phlegmasiæ presenting all the shades, in fact, such a diversity, that no identical character exists. According to M. Bretonneau, the identity consists in a considerable tumefaction of the tonsils, accompanied with an œdematous swelling of the tissues surrounding the larynx and trachea, together with a formation of pellicles, that are detached by flakes like the lichens of a tree, and in a propagative disposition towards the pharynx, the larynx, the tra-

chea, in short, all the surfaces that the disease invades. But wherefore assign to this shade exclusively the name of gangrenous anginæ, since all the serious anginæ are liable to have it? Wherefore endeavour to shew that the exudatory anginæ that is confined to the larynx is any other than croup, and call it pseudo-croup? Wherefore limit the true croup to cases where the exudation commences in the velum palati and tonsils, and successively reaches the pharynx, the larynx, the trachea, and bronchi? Wherefore except from this denomination cases in which the exudation is only formed in the last named parts? There is something arbitrary in this. Wherefore also say that the disease always commences by the velum palati and extends downwards, whereas there are instances in which it begins in the larynx and mounts into the mouth? Everything is possible to inflammation: it proceeds in all directions: in no epidemic has it a constant direction: it goes on guided by a host of circumstances, difficult to fix upon, but not the less existent; these, the more we observe, the more we learn to attain and appreciate. In short, it has no determinate form, except in decidedly contagious diseases, such as small and cow pox; and even in these the contagious inflammation, which has its fixed form, must be distinguished from the additional inflammation, which has it not. These questions, however, are only cleared up by facts and comparisons, and you must not imagine that medicine is learned in an instant by merely didactic processes.

As regards the phlegmasiæ that are developed in the gums, and have been improperly called scorbutic, they actually exist, and are accompanied with an exudation that approximates them more or less to the preceding affections. But I do not see why they should be assimilated to the suffocative anginæ rather than to any other, for the same reason that I do see why less connexion is said to be found between them and the suffocative anginæ, which is confined to the larynx, than that which suffocates after commencing in the velum palati. Undoubtedly, the most dangerous of these inflammations is that which produces false membranes in the air passages; but no natural differences between them can be established by taking their starting point as the basis of distinction. Divisions of these inflammations may be established, taking them from the highest to the lowest degree of phlegmasia; in fact, they may present themselves in a purely sanguineous, membranous, or phlegmonous form, as also in a secretory form, accompanied with an exudation, proceeding from an irritative action fixed in the mucous follicles, and producing false membranes. In this second form subdivisions have been made: some being referred to pure and simple catarrh, others to something more intense, and different when

the exudation acquires the consistence of a thick, adherent crust, and constitutes the affection that has received the especial name of membranous anginæ (*angine couenneuse*). Some have been characterized by a much less tenacious exudation, peeling off like lichens, and more particularly by a propagative property, that sometimes causes them to extend into the respiratory and digestive passages. Finally, those have been made distinct that appear in the gums, and are accompanied with an exudation that covers the gums, and forms a white fringe at the roots of the teeth. This last shade, formerly called scorbutic gangrene, has been united, by M. Bretonneau, with the propagative lichenoid, under the name of diphtheritis. In this manner we have A, the sanguineous form, with 1, the membranous, and 2, the phlegmonous shade; B, the secretory form, with 1, simple catarrhal shade; 2, exudatory, dense, and tenacious shade (*angine couenneuse*); 3, exfoliating, or lichenoid shade (*diphtheritis*), with which is connected the scorbutic phlegmasia of the gums, and epidemic croup.

According to a new theory of these inflammations, the name of croup has been denied to that which is confined to the internal surface of the larynx, and produces false membranes; and it has been proposed, to give it only to the secretory inflammation of that organ, consequent on pellicular inflammations of the mouth and pharynx. To the former of these aphthæ have been approximated, and considered as an inflammatory affection of the mouth, not primary, but dependant on an internal influence; consequently all connexion between them and diphtheritis, between them and scorbutic gangrene, is rejected. This diphtheritis has been assimilated to the so called malignant or gangrenous anginæ of the ancients, the model of which was given by *Aræteus*; and its author has considered as appertaining to it, on one hand, the croup, such as he thought it to be; and, on the other, the scorbutic phlegmasia of the mouth, whilst he has separated from it the mucous concretion from simple catarrh, as well as the more cohesive one, in order to group them with an imaginary stridulous anginæ, or false croup, described by certain authors, and with the asthma of *Millar*.

Of the causes, it has been said that they have been divided into those which produced ordinary inflammation, and those producing diphtheritis; those of the latter being specific, hidden, inaccessible. Whenever it has been difficult to fix on a directly demonstrable cause, another has been sought for by deduction—deduction, that rock upon which almost all the ancients split, and which very many of our modern medical men are unable to avoid. Of this we have an instance, in the history of the dis-

ease now under consideration. The modern epidemics of it that are quoted, and which are to be found in M. Bretonneau's work, no where exhibit the proof of a specific cause, and comprehend very diverse affections, so as to render it impossible to find an uniform epidemic form in them, and consequently to attribute them to a contagion. This work has been highly praised, and, no doubt, with reason; but, as it is not free from imperfections, and as, moreover, it is not proper that you should receive ready-made verdicts from any one—I shall take the liberty of criticising it, if not in detail, at least so as that you shall read it with advantage.

Diphtheritis, an imaginary entity, founded on the approximation of three particular shades of exudatory phlegmasiæ, to the exclusion—God knows wherefore—of other exudatory shades, has been assimilated to the malignant gangrenous angina of Areteus. Applying to Areteus we find, that he does not only make mention of a simple phlegmasia of the gullet, but of a very extensive affection developed together with symptoms of gastro-enteritis, and soon after accompanied with an affection of the throat; in short, a species of typhus, with a predominance of guttural phlegmasia. If we next consult the other epidemists, they tell us pretty nearly the same thing: some of them, however, give the name of gangrenous sore throat to certain phlegmasiæ of the larynx, that have never exhibited any mucous excretion of the mouth; of these authors the majority have seen the affection commence with a febrile state, of several days' duration. In M. Bretonneau's interesting work mention is also made of cases in which the fever existed previous to the formation of crusts. Now what do these days of antecedent fever, in which no inflammation of the throat exists, mean? There must be a cause for this fever; if it be not in the throat, it is elsewhere: look to the functions, see if there be not bronchitis, pneumonia, gastro-enteritis, cerebral congestion, rheumatism, &c., and you will finally discover the starting point. But nothing is proved with regard to the supposed disease, when it is affirmed, that three or four days of fever are necessary before it is characterized. It is not thus that physiological physicians express themselves; they merely say, that the cause of this fever is a gastro-enteritis, such as it is observed in low and moist places, among cold and moist air, miasms, &c., influences which act on all the mucous membranes, but especially on the throat; and they add, that if this gastro-enteritis is stayed in its commencement, suffocation is prevented. In support of these assertions they bring numerous facts, but no attention is paid to those facts; is mention made of gastro-enteritis, people seem to be offended at the

term, and shrug their shoulders as if to signify that they are labouring under some vision or hallucination. On dissection, the victims of this gastro-enteritis exhibit traces of it, as might be expected. But others begin by supposing, that these traces do not exist; they open the throat, they search in the lungs, causes of compression are found in the trachea, or on the tonsils—the lungs may be even somewhat indurated; they declare that the patient died of these lesions. True, they agree, after venturing to examine the digestive canal, that some portion of it was red, softened, pulpy, and exuded blood, or bloody serosity; but, as they had given calomel internally, and were, moreover, certain that calomel is a strong poison that kills dogs, they say that these disorders indicate a mercurial cachexy of the digestive canal, instead of recognising this inflammation as the primary basis of the disease, and the effect of the treatment. Such are the facts on which they proceed, when they go to show the seat and nature of diphtheritis!

When they * come to the treatment, they begin by denying the good effects of sanguineous emissions:—because they have employed them? not at all. To prove their inutility they quote an ill digested case, in which they have been used at too late a period, after the phlegmasia had invaded several mucous membranes over a great extent: but in this case nothing succeeded, not even the specifics, whose success they are so fond of lauding. They even insult the reader by quoting three or four cases in which no bleedings were made, to prove that bleedings are of no use! Calomel, calomel exclusively, is cried up for its power of arresting the progress of diphtheritic secretion in the bronchi and digestive canal. Subsequently, after giving a few instances, they refute themselves in a second or third treatise, by saying that calomel is a poison that causes dogs to die in a cachectic state. Fumigations are lauded, because they imagine the disease to have commenced in the tonsils, whereas it appeared in another point, and is already degenerated on its arrival there. The disease making rapid progress during these fumigations, they give them up; and next they administer abundance of stimulants internally, at the same time that they cauterize the tonsils with muriatic acid, until at length, as the patients are dying, it is impossible to say whether their death is owing to the intensity of the disease, to the cauterization, to the mercury, or to the fumigations, so utter is the confusion. Alum,

* The reader will not forget that M. Broussais is all this time criticising M. Bretonneau's work; every translator of French will perceive my motive for rendering the "on" of that language by "they;" it is a polite expression which we might do well to introduce.—J. M. G.

an old remedy, is then substituted for muriatic acid, this being considered too active; but this alum has scarcely a favourable case to support it; besides, what shall we say of the action of a substance given simultaneously with stimulants whose effect is to complicate or neutralize its own powers! The mortality of the epidemics related by authors they consider as the result of defective local treatment, and in the majority of instances in which they have treated patients by local means they have failed; but they never dream of attributing this mortality to the ignorance of the ancients, or to their own ignorance of the phenomenon of inflammation. For this vast and important phenomenon they wish to substitute some sort of entity; yet it is this which, neglected and misunderstood as it has been, has produced those depopulating plagues that raged in times past, and would not have been so murderous had inflammation, instead of being allowed to go unmolested or unprovoked, been arrested. Now-a-days, with the physiological doctrine, they could cause no such disasters, nor carry off a third of the human race; in fact, have not the diminutive lights borrowed from this doctrine, and which have penetrated the regions of the North, latterly prevented the cholera from making the horrid strides effected by former epidemics? Doubtless, with greater attention, it would have done so still more effectually; and so it would be with diphtheritis, were people willing to make the necessary inquiries concerning the local causes of epidemics; but they content themselves with stating a few isolated and obscure facts of contagion, which are contradicted by others and more numerous ones of non-contagion, and from them they deduce the existence of a mysterious principle that generates the disease—a sorry deduction, evidencing the self-conceit of man, who prefers to *wander* in the false paths that are open to him rather than be *led* into the true! As to their treatment of diphtheritis, as it is nothing more than a mixture of stimulants, that act in different ways and in a confused manner, I can understand nothing of it, and really know not what to think about it. Indeed, how is it possible to comprehend men who proceed without method, who transform diseases so as to render them unintelligible, who create artificial ones, and are unable to distinguish the one from the other, the good from the evil they have enacted? For my part, I shall never agree with such; as soon as I see inflammation, I try to crush it in its cradle; they, on the contrary, cherish it. I except, however, a disease which they have thus fomented in its origin, and which is presented to me in a deformed state; all descriptions of that kind are facts, I allow, but not such as nature offers them and such as we are in the habit of meeting them.

Do they compare croup with diphtheritis, equally incomplete descriptions are given,

and the faults in deduction are equally numerous. Croup is regarded as forming part of the disease; but how and when? this they do not state. They only are strenuous in comparing the concretions of the malignant angina of the ancients and those of scorbutic gangrene with those of croup, and they thence deduce characters of an identity that by no means ensue; in fact, the concretions have not twice together the same cohesion nor the same thickness, these qualities being dependant on the inflammatory movement, on the manner in which it acts, on the individual dispositions, on the peculiar condition of the mucous follicles, &c. Though cases alone are cited, in which the excretion of the membranes resembles lichens, others might be quoted in which it is hard and thick. What shall we say of a theory founded on such distinctions, and in which the mode of development of croup is made altogether subordinate to the mode of development of the pretended diphtheritic inflammation? This disease is ordinarily allowed to go on in order to wait for its characteristics: the patient experiences three or four days of fever, during which nothing is done: a sore throat appears: some lichenoid mucous efflorescences supervene on the tonsils, and an œdematous swelling of the throat. Arrest these symptoms, the disease stays there, and there is no fear of croup; but if it be not arrested the mucous excretion begins to spread towards the larynx, and the croupy symptoms then come on. But wherefore insist upon looking to this consecutive croup only to make it an essential croup? When it exists it must be proved—so; we deny no facts, but the deductions from them, such a consecutive croup *may* exist—there is no difficulty in admitting it, but is that any reason why, in other circumstances, during the same epidemic, perhaps in the same house, a person may not begin to have a hoarseness without having any previous fever, that he may not cough and have a râle, that he may not expectorate a mucous pellicle and shortly be in the agonies of asphyxia? Is that any reason for not giving such an affection a distinct rank? Wherefore consider it as a slight disorder scarcely worthy of notice? Wherefore does it not merit the attention of a nosologist as much as any other affection? Wherefore, in short, look upon it as a false croup, and only consider *that* the true one which occurs when a great number of the patients have been affected in the abdomen and chest? Moreover, in leaning upon authors, all the facts they give should be borne in mind. Now, Aretæus, Huxham, and several others, have seen this disease commence by the gastric apparatus, and though they treated of it in a manner anything but rational, they bore witness to the advantages derivable from blood-letting and leeches—a circumstance that should not have been—as it was—neglected.

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 128.)

In the treatment of permanent stricture of the urethra, two great classes of agents have been employed—dilatation and destruction.

In the earlier periods of the history of surgery, we know of only one mode of treatment, and that only because straight metallic sounds have been found in Herculeanum, and we must therefore presume that they were employed—and because we have representations of such instruments in Arab authors.

After this period, the practice of the art in this particular appears to have relapsed into much of the barbarism by which, in the middle ages, society was characterised. During these times, the opinion commonly established was, that “stricture” was occasioned by the existence of “carnosities” within the canal, and that these could only be destroyed by escharotics, which were to be brought into contact with the diseased structure, by means of extremely rude instruments, which afforded no protection to the healthy portion of the canal.

During the same period, cutting instruments appear to have been invented for a similar purpose, and they were, it is said, employed upon the “sacred” person of Henry the Fourth of France.

Up to this time we have seen that three several modes of treating stricture had been employed, dilatation, cauterization, and cutting instruments.

The sixteenth century introduced considerable improvement into the manufacture of bougies, and their sale became sources of wealth and celebrity to many persons; but the other two modes of treatment appear to have fallen into disuse, in consequence of the mischief they so frequently occasioned.

In place of the rude escharotics we have mentioned, we find, in the next century, a substitute in the medicated bougies of Darian, the fame of which was long celebrated throughout Europe; and they procured for him, it is said, 60,000 francs per annum.

Little further change appears to have been introduced into the treatment until the time of John Hunter, who first responded to the necessity of affording protection to the healthy portion of the canal during the introduction of caustic, and substituted for the rude escharotics of former times, the lunar caustic. At a later period, he appears to have become bolder, for he dispensed with the canula, and used bougies armed at their point with the lunar caustic.

The same treatment was performed with success by Sir E. Home.

For the nitrate of silver, Mr. Whately substituted the caustic potash, which possessed two serious objections, that of being ex-

trremely deliquescent and therefore likely to injure the healthy portion of the canal, and that of increasing, in many cases, the irritability of the canal, while the nitrate exercised a sedative influence.

Great as the merits of Hunter unquestionably are—if any attach to the invention of the armed bougie, they clearly do not belong to him.

The method practised by Alphonso Ferri, in 1550, was to attempt the cure by bougies; if they failed, he introduced into the canal a hollow bougie, and through that a sharp pointed stiletto, with which he penetrated through the stricture, but when both these means failed, he applied caustic fixed to the end of a bougie; this caustic was not, it is true, either the caustic potash or the nitrate of silver, for these were then unknown, but red precipitate, orpiment, or verdigris, incorporated with some kind of mucilage.

At this moment, we have still three methods of treating the disease, bougies possessing, we believe, all the improvement of which they are susceptible—caustic, carefully guarded by instruments, which are modifications of Lallemand and Phillips’—of that which was invented by Ducamp; and we have cutting instruments by Physick, Dorsay, Despiney, Stafford, and others, modifications of which—for want of anterior ownership—we must refer to Ferri; the consecutive use of bougies, we must refer to Mayenne, who employed them on Henry the Fourth of France, in 1603, after the use of the cutting instrument.

Having enumerated the methods of treatment which have been employed, and the modifications to which, from time to time, they have been subjected, we have next to consider the most important part of our subject—what is the treatment which ought to be employed, in those cases of stricture which are dependent upon the existence within the canal of indurated masses of matter, and to which we apply the term *permanent*?

Happily, we live in times when we have sufficient experience to enable us to express an unprejudiced opinion with regard to the value of dilatation.

We have no difficulty in stating our belief, that only a very few cases of stricture are completely beyond the reach of relief by dilatating bodies, but we are at the same time bound to say, that only a very small number of cases can be cured by such agency. The reason of this is obvious, but we do not recollect to have seen it so clearly stated as in the work of Mr. Phillips, to which we have already alluded. “This disease of the mucous membrane appears to be produced by the distention of the areola of the tissue by concrete albuminous matter.”

“In the progress of induration (from the deposition of new matter, and from the consequent increase of density) an obstacle gradually presents itself to the free ingress of

fluids into the organ, and the indurated tissue then loses more or less of its vitality." "If the change produced by induration be accompanied by what I have presumed it is, a decreased supply of blood, and a consequent less energy of action than was possessed by the tissue in its natural state, and if, by the same means, there be obliteration of the cells of the tissue, and if it be of long standing, we can hope to remove it only by mechanical or chemical destruction of the tissue."

Theoretically, then, we should not expect to remove such a disease by bougies, because absorption is scarcely possible; practically, we have undeniable evidence in the experience of all men who have extensively employed the agent, that old standing disease of this kind is only relieved for a time: that the interval between the periods when it is necessary, even through the whole of life, to introduce the dilating body, rarely exceeds one or two months.

The length of the interval is to some extent dependent upon the mode in which the dilatation is practised—if it be done very rapidly, the disease will soon re-appear; if it be done very gradually, the interval is considerably extended.

We have lately had occasion to become acquainted with the method of dilatation employed by Mr. Phillips, and if subsequent experience shall confirm that which has been already obtained, we have no hesitation in saying that a vast improvement will have been introduced in this mode of treating stricture.

The principle is never to use an instrument which will not readily pass through the stricture, and never to employ a yielding substance. By this means the wedge system is not employed, and if the dilatation be effected at all, it must be by lessening the bulk of the induration.

The instrument (a flexible metallic sound) remains in the urethra on an average at least two hours; the time must, however, vary with the circumstances of the case.

He does not state that in all cases the cure is complete, but that the interval is always greatly extended. We happen ourselves to know three or four cases where from four to six months have elapsed without any apparent diminution of the stream; and of those, two were very advanced cases.

We, therefore, feel ourselves called upon to urge the importance of this treatment on the profession generally, and upon those whose opportunities of treating these diseases are frequent.

We can scarcely expect that any modification will render the mode of applying caustic more harmless than those at present employed, of which we have already spoken. So far, therefore, as the protection of the canal is concerned, the system appears unobjectionable. So far as the principle of

destroying the indurated matter is concerned, no more comment is necessary.

The instrument commonly employed is the armed bougie, to which we have serious objections: first, because too frequently the healthy mucous membrane is injured by it, in its passage towards the stricture; and next, because, even under the most favourable circumstances, until the whole of the contracted matter is destroyed, it is very difficult to ascertain whether the instrument have taken a right direction. This matter is frequently so considerable, that many weeks are passed before the necessary destruction is effected.

These two objections to the treatment by the armed bougie, are avoided by the method of application pursued by Lallemand and Phillips; the portions of canal in front of the stricture is protected, and the application of caustic is made upon the interior of the stricture; so that the moment the eschar is thrown off, the stream of water is by so much increased, the patient's confidence raised, and the medical man assured that the instrument has been correctly directed.

It remains for us to inquire, whether there be any objection to the use of caustic when judiciously applied. Our own feeling is, that there is often much difficulty in preventing consecutive contraction; we can scarcely conceive that a considerable destruction of tissue can occur, without producing a tendency to contraction. Our own experience has convinced us that this tendency is strong, but our conviction is, that, with care, it may be overcome.

We have under our observation such cases, and there is a considerable number of similar well authenticated cases upon record.

We find that this is the impression of other medical men, who are frequently accustomed to employ caustics.

It was suggested to us by Mr. Phillips, that this, the most serious inconvenience attending the use of caustic, might be avoided in the following manner:—by applying only a small quantity of the remedy upon the membrane; that the stimulus thus produced disposed the absorbents to act; that this action is kept up by the presence of such a flexible metallic instrument as would easily pass, and which is permitted to remain in the canal one, two, or more hours daily. He stated further, and certainly the analogy of similar applications upon the mucous membrane of the mouth would appear to confirm the justice of his opinion, that, after such a use of the caustic, there was no tendency to cicatrix—no disposition to consecutive contraction.

What then, if any, are the advantages of caustic over dilatation? In a few words, we apprehend them to be the following:—that caustic is applicable in many cases

where, from extreme irritability, dilating instruments cannot be used; that the treatment does not occupy so long a time; and, that when properly used, the disease is permanently cured. There remains for consideration yet one method of treating stricture, it is by cutting instruments; and we confess we do look with considerable abhorrence at this mode of treatment. We believe that it is now very rarely employed; and we do not think that any modification of a pointed cutting instrument could justify the resurrection of that system.

We speak thus decidedly, because we have witnessed its disastrous effects in this and other countries.

If the objections to it be of such a serious nature, what are its pretended recommendations?—None. In those strictures the orifices of which are too small to admit a bougie, room is made for it by means of the instrument; and in cases of retention, if there were no better mode, we might hold that its employment was justified, because, too, we have a great horror of forced catheterism, and because puncture of the bladder is not favourably regarded by the profession but, happily, these are not the only modes of relieving such a state. We have never seen a case of retention which was not susceptible of relief, either by the remedies usually employed in such cases, or by the following method:—introduce a canula into the urethra, and bring it into contact with the stricture, adapt to it the pipe of an elastic gum bottle filled with warm olive oil, apply a sufficient quantity of force, a portion of the oil will pass, and urine may then be expelled. Is it applicable to extremely narrow strictures, those, in fact, which will not admit the smallest size bougie, but which do not occasion retention? We again say no; for we have scarcely ever known a stricture which would resist the steady pressure of a bougie when kept in contact for two or three hours. Is it a method with which, putting out of the question its inconveniences, strictures may be cured? Decidedly not—it does not destroy the induration—it does not stimulate it to any extent, at best it can only open a way for the bougie.

We are, therefore, entitled to state that permanent stricture can rarely be cured by means of dilatation only; that, with care, they may be commonly cured by means of caustic, employed in the way we have described—and that the application of the cutting instruments, now used in this and other countries, is not only dangerous, but as near as may be, useless.

Foreign Medicine.

Present State of the Medico-Legal Doctrines concerning Insanity in Germany. By M. Taufflieb.

IN this essay my object is to lay down the doctrines and facts that are calculated to solve a certain number of medico legal questions that are at this time the subject of scientific discussions in Germany. These questions refer to monomania, mania, defective intellect, loss of hearing and speech, drunkenness, somnambulism, and some events of the puerpural state. And first, of

Monomania.—Since the time when the publications of Pinel, Esquirol, and Georget threw light on the various kinds of mental alienation, and particularly monomania, the German state-physicians have been actively engaged in comparing the facts observed in their own country with those advanced by the French authors, and the consequence has been that disgraceful prejudices have disappeared under the influence of which many unfortunate lunatics were formerly punished when they ought rather to have been the objects of medical treatment: fortunately no such exhibitions are now seen in Germany.

The partial mania designated *monomania* by M. Esquirol, may exist with or without lesion of the intellect; the numerous facts published in later times allow no room for doubting the fact. M. Marc proposes to term the former *rational monomania* (*monomanie raisonnée*), and the latter *instinctive monomania*. This distinction is now-a-days admitted in Germany by Clarus*, Hoffbauer†, Masius‡, Haindorf§, Grohmann||, Conradi¶, Reil**, Wildberg††, Schulge‡‡, Heinroth§§, and indeed by all the German medical jurists.

* Henke's Journal für die Staatsarzneikunde, 1824.

† *Médecine légale relative aux Aliénés.*

‡ *Handbuch der gerichtl. Arzneiw.* 1823.

§ *Versuch einer Pathologie und Therapie der Geistes Krankheiten.*

†† *Lehrbuch der gerichtl. Arzneiw.* 1824.

‡‡ *Psychische Antropologie.*

§§ *System der Psychische-gerichtl. Médécine*, 1825.

Henke, who has hitherto denied the existence of an instinctive monomania in its absolute meaning, admits all the facts advanced by authors in proof of a specific lesion of the will; he acknowledges that the subjects of the observations have not acted with liberty, and could not be responsible for their actions: "but," says he, "we are only to behold in this anormal and morbid condition of the affective faculties and the will, the starting point of the disturbance of the intellectual functions during the time of their action, a disturbance that is the only excuse for the violent proceedings of the unfortunate beings in question. The distinctive point of the moral being, man, from the brute, is the enjoyment of a degree of reason that renders him capable of regulating and constraining his instinctive impulses and the depraved desires that may light up in him: so long as this reason is not obliterated or altered, man is responsible for his actions, however violent may be the tendency that drives him to the commission of a criminal act. In seeing men of mild temper, of irreproachable, and even virtuous conduct, urged, in spite of themselves, to the most extraordinary acts of violence, for instance, make murderous attempts on those whom they most love, it is impossible to deny that at the time of the act, at least, some disturbance of their intellectual functions must have obtained, although these patients may have appeared, immediately before and after the act, to be in possession of their entire reasoning powers." In favour of this opinion, Henke quotes the authority and experience of M. Esquirol, who, he says, refers the mania without delirium of Pinel to monomania, that is, to a partial delirium produced by a predominant and exclusive idea. But he evidently mistakes the tendency of the latter author's words, who says that "monomania exhibits two well distinguished forms; in one case the murder is induced by a deep but delirious conviction, by the exaltation of the wandering imagination, by false reasoning, or by the passions in a state of delirium; in the other case, the homicidal monomania presents no appreciable alteration of the intellect, or the affections; the patient is entirely drawn on by a blind instinct, by an idea, by an indefinable something that leads him to kill.

M. Amelung, who appears to have fully adopted Henke's idea, regards even the act committed in the majority of instances, of instinctive monomania, as a proof of insanity. He quotes a case in which a lady was frequently tormented by a horrible desire to throw her child through the window, and on this account never dared to approach a window for fear of yielding to her homicidal propensity. He asks, whether such a desire in a mother, who tenderly loved her child, does not suppose an actual aberration of the intellectual functions*.

M. Hartmann, whose opinion seems somewhat to resemble the above, conceives of instinctive monomania, in the following manner:—In mania, without delirium, he says it is not deceptive dreaming that leads the mind to insane acts, but morbid sensations, dependant on an alteration of the general sensibility that violently take possession of the mind, absorb all its attention, prevent its reflecting on other subjects, and in this manner, without disordering the reason, nevertheless control its activity during a certain portion of time. The outbreaks of fury that sometimes accompany this state, are in part the result of extraordinary efforts, made by the mind, to rid itself of an insupportable sensation, and in part are owing to a super-activity of the determining faculties—an activity that strives to find an outlet in acts of violence†.

The divergence of the opinions above quoted, it will be readily seen, do not go to the root of the medico-legal question of monomania: we have to deal only with a psychological distinction, having reference to the explanation of a series of well ascertained and universally admitted facts. *Are the will and the affective faculties capable of being disordered, so as to induce immediately of themselves, or mediately by a temporary disturbance of the reasoning power, the abolition of moral liberty?* Considered in its whole latitude, the question is solved in the affirmative by all the German medical jurists; and it is wholly on this question that the modern medico-legal doctrine, concerning instinctive monomania, rests. It will be allowed, that the essential practical point is to admit that moral liberty may be destroyed, not only by a primitive abolition of the intellectual functions, as evidenced

* Henke's Journal, 1829, † Ibid.

by extravagant ideas and actions, but also by a specific lesion of the affective faculties in men who otherwise enjoy the integrity of their reasoning powers. Besides, who can assert that reason in such shall remain altogether unhurt in the midst of a general anguish; at the time; for instance, of an action, the idea of which alone suffices to distract, to overthrow the whole range of the moral powers.

(To be continued.)

PETITION OF THE LICENTIATES AGAINST
THE COLLEGE OF PHYSICIANS.

[Press of matter prevented us last week from inserting the following document, the substance of which formed the topic in our last leader. The petition might have been signed by at least 200 physicians, but this was considered unnecessary.]

The Petition from the Committee of Associated Licentiates, presented by Henry Warburton, Esq. M. P., August 17th, 1835.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland in Parliament assembled. The petition of the undersigned physicians, representing the interests of a large portion of those practising in London, humbly sheweth,

That certain *bye-laws*, recently made by the *Royal College of Physicians*, relative to the general management of that body, and more particularly to the admission of the licentiates into the fellowship, are fraught with injustice towards the majority of physicians practising in London, and tend still further to injure and degrade the order of licentiates, and to perpetuate the grievances which have so long existed—and which *bye laws*, your petitioners submit, are illegal.

One of the *bye-laws* enacts that a council of twelve fellows shall be chosen, on whom is to devolve some of the most important duties of the corporation; for instance, the nomination of censors, and of licentiates for the fellowship, is exclusively to originate with them, afterwards to be submitted to the ballot of the commonalty.

Your petitioners respectfully submit that, the mode of keeping up the succession of this council is framed on a close and narrow system of monopoly and exclusion, exhibiting some of the worst features of a close corporation; and that the power granted to the council of determining the number and the individuals among the licentiates to be proposed is, in the highest degree, objectionable; that it is open to personal and to party prejudice; that it will lead to the worst species of favouritism, by giving an undue influence to the fellows composing the council; and that it will tend to produce servility and moral degradation.

Your petitioners beg leave to represent, that inasmuch as no corporation can make

bye-laws, which limit or control the powers granted by the charter to its individual members, the *bye-law* of the College, which deposes exclusively to the council the power of determining the number, and the individuals among the licentiates to be ballotted for by the fellows, vitiates the just right of every fellow to propose or vote for any, or every, licentiate into the fellowship, whom he may think proper: thus, also, if the said council do not propose or make any nomination, no fellow can ballot, since no licentiate can be proposed for the fellowship except by the council.

Therefore it appears to your petitioners, that the right of each individual corporator to keep up the succession in the terms of the charter, is in fact destroyed, and consequently this *bye-law* is illegal.

The charter ordains that the censors are to be elected by the president and College, or commonalty; but in direct violation of this, the *bye-laws* deposes to the aforesaid council, the power of nominating the censors, and the fellows are thus constrained to ballot exclusively for those so nominated; consequently the right of the corporators to elect the censors is illegally infringed upon.

Your petitioners beg leave to state, that they view with surprise and regret, this puny attempt at self-reform, made by the College of Physicians—in the face of the great mass of evidence produced before the committee of your honourable House, which so completely demonstrates all the grievances complained of, and substantiates every allegation contained in the petitions presented to both Houses of parliament, in the two last sessions, by your petitioners and others.

Your petitioners, therefore, earnestly pray your honourable House to interpose its influence, in order that the said *bye-laws*, recently enacted by the College of Physicians, may not receive the sanction of his Majesty's Commissioners of the Court of Chancery, and the Lords Chief Justices of the Courts of King's Bench and Common Pleas; and that your honourable House will grant such other relief as in its wisdom it may think fit.

And your petitioners, &c.

John Sims, 37, Cavendish Square, *Chairman of the Committee.*

Reviews.

A Treatise on Pulmonary Consumption; comprehending an Inquiry into the Causes, Nature, Prevention, and Treatment of Tuberculous and Scrofulous Diseases in general.
By James Clark, M.D. F.R.S. 8vo.
pp. 399. London: Sherwood & Co.

(Continued from page 53.)

CHAP. 6 treats of diseases which attend and complicate consumption.

As the disposition to the formation of tubercles is not confined to the lungs, but exists as a morbid state of the general constitution, we may expect to find other organs tuberculated though the lungs are generally soonest and most extensively affected.

"There are also other morbid lesions, particularly of the mucous membranes, which complicate, and are so intimately connected with, consumption, as apparently to form constituent parts of it; and it is worthy of remark, that some of these secondary affections are occasionally so prominent as to mask the primary and most important affection, which is only made manifest by examination after death. In some cases, for example, the diarrhoea is so severe, and assumes so much the character of chronic dysentery, as for a time to throw into the back-ground the less evident symptoms of pulmonary phthisis: but, on examination after death, although the intestines are found ulcerated and otherwise diseased, the lungs are in general so much more affected, as to leave no doubt that they were the primary seat of disease. Again, disease of the larynx occasionally produces such marked symptoms as to be taken for the principal affection, even when the lungs are extensively tuberculous."

The most important complications of phthisis are—

Diseases of the Organs of Respiration.—The mucous membrane of the air-passages is generally diseased to a greater or less extent. *Ulceration of the epiglottis* usually occurs late in the disease, and, when slight, is not indicated by any particular symptoms; the larynx, however, is commonly affected in a similar manner. The lingual surface of the epiglottis is rarely ulcerated; Louis found it so only in one case, in which the symptoms were pain in the region of the os hyoides, and difficult deglutition, fluids being frequently ejected through the nostrils in the attempt to swallow them; the last symptom is considered characteristic of inflamed epiglottis, but does not always at-

tend it. In some cases the epiglottis is cedematous. *Ulceration of the larynx* is a frequent complication. It usually occurs at an advanced period; occasionally, however, symptoms indicative of it appear before those of the pulmonary affection are very evident. The symptoms of ulceration in the larynx vary according to its site, and generally keep pace with its extension; they are sometimes so prominent as to lead to the belief that the larynx is the chief seat of the disease; but our author agrees with Andral in thinking that the disease termed laryngeal phthisis is in most cases pulmonary consumption masked by an unusual predominance of the laryngeal affection, the emaciation, hectic fever, and other important symptoms being still referable to the pulmonary disorder. Ulceration of the larynx is almost constantly attended with hoarseness, and sometimes with aphonia; there is generally pain in the site of the os hyoides, which is often severe when the ulcerations are deep; cough is also present, accompanied with a peculiar harsh, grating sound, or sometimes one resembling a kind of whistle. *Ulcerations of the trachea* do not give rise to any particular symptoms: Louis has found no characteristic indications of their existence even when they are severe and numerous. Ulcerations of the trachea are found almost exclusively in phthisical subjects: they are frequently confined to one side, which, according to Andral, invariably corresponds with the diseased lung, or with that which is most so when both are affected. In the larger bronchial tubes ulcerations are much less frequent than in the larynx and trachea; in the minute ramifications of the air tubes, however, they are, according to Dr. Carswell, extremely common. Louis found ulceration of the epiglottis and larynx in *one-fifth*, and of the trachea in *one-third*, of the cases of phthisis he examined, whereas he found it only in one out of a hundred and twenty-two cases of other chronic diseases—establishing a close relation between these lesions and pulmonary consumption: he also found that such ulcerations occur more frequently in men than in women, in the proportion of two to one. The *affections of the pleura* attendant on phthisis, consist in the effusion of coagulable lymph, causing ad-

hesions between the pleura pulmonalis and costalis, and perforation of the pleura, with consequent escape of air and purulent matter into its cavity.

"Adhesions almost constantly accompany the formation of tubercles, and their extent corresponds with that of the tuberculous disease. In only one case of one hundred and thirteen examined by Louis, both lungs were free from adhesions; the right was exempt in eight cases, and the left in seven: in twenty-eight they were small and easily broken down, and the caverns were either small or wanting. In the other two-thirds, they were dense and firm, and accompanied with large excavations. In two cases, where the lungs contained but two excavations, the adhesions existed only over the parts corresponding with them.

"These facts show, in the clearest and most satisfactory manner, the intimate relation of tubercles and adhesions as cause and effect. From the adhesions being often confined to the spot corresponding with the tuberculous excavations, and from the absence of all appreciable signs of inflammation during their formation, it is probable that the lymph of which they are composed is frequently poured out from the vessels with little or no irritative action. They sometimes present the appearance of semi-cartilaginous crusts, covering the summit of the lungs, and in other instances they are changed into true tuberculous matter. If the ulcerative process goes on in the walls of the caverns till the intervening pulmonary tissue and pleura are destroyed, these new formations constitute the proper walls of the caverns; and if the process advances, these also may be destroyed, and the matter point externally."

Perforation of the pleura is one of the most distressing accidents which occur in the progress of phthisis.

"It is characterised by the suddenness of its occurrence, and by the marked symptoms to which it gives rise—sudden pain in the side affected, great oppression of breathing, and extreme anxiety, which are speedily followed by symptoms of acute pleurisy. This accident resembles the perforation of the intestine, the escape of feculent matter into the cavity of the peritoneum, and the violent inflammation of that membrane.

"Perforation of the pleura for the most part occurs in the advanced stage of the disease when the patient's strength is greatly reduced, and in general proves speedily fatal. It has caused death in twenty-four hours; but when the symptoms are less acute, the patient has lived for thirty days; and Dr. Stokes states a case where the patient survived five months. A sudden attack of pain, on one side of a phthisical patient, with much oppression and anxiety, may be considered as

indicating the accident. Louis, however, gives a case (xliv) where oppression and anxiety, without pain, marked its occurrence.

"Perforation of the pleura may take place under two circumstances: a tuberculous cavity, which communicates with the pleura by means of the perforation, may or may not communicate with the trachea. In the former case we have generally an effusion of air and fluid into the cavity of the pleura, connected with which there is present a peculiar symptom called *metallic tinkling*, or a clear fine sound resembling that produced by the falling of a pin on glass, and heard when the patient speaks or coughs. When there is no communication between the tuberculous cavity and the pleura and bronchi, or when there is an effusion of air only, or a very small quantity of liquid, it was Laennec's opinion that there could be no metallic tinkling. Dr. Williams, however, has shown the fallacy of this opinion, and that neither communication with the bronchi nor liquid effusion is necessary to the production of the phenomenon: he considers it to be nothing more than an echo or resonance which any sound or impulse propagated to a cavity of a certain form may produce.

"Of eight cases of perforation which occurred to Louis, seven were on the left side—a circumstance which he attributes to tuberculous disease being more frequent on that side, and often more advanced than on the right.

"Perforation of the pleura generally takes place over a tuberculous abscess or cavern of considerable extent; yet cases occasionally occur in which a small softened tubercle immediately under the pleura bursts and discharges its contents, and this may be one of a very few contained in the lungs. Andral mentions a case of this kind where the lungs contained only five or six tubercles. In such cases, from the small size of the cavity, little or no effusion of pus or other matter takes place, and, consequently, the perforation is not necessarily followed by pleuritis.

"Great accumulation of air in the pleura gives rise to the most distressing dyspnoea, and generally soon proves fatal, from impeded respiration. I lately met with a remarkable example of this kind: tuberculous disease was far advanced in the right side, while the left was but little affected; the patient was suddenly attacked after a fit of coughing with severe dyspnoea: the left side was found tympanitic, the intercostal spaces were distended, and no respiratory murmur could be heard. An opening was made between the intercostal space of the fourth and fifth ribs, from which the air rushed out with great violence, giving considerable relief to the patient. Death, however, took place in twelve hours from the commencement of the attack. On opening the body, the right lung was found everywhere adherent and full of caverns and tubercles; the left was, for the most part, free; but in one portion a dense, though not extensive,

adhesion had been partly torn from its attachment, thereby causing a rupture of the pleura over a very small tuberculous cavity, through which the air had passed freely from the bronchi into the chest, giving rise to all the distressing symptoms. The history of this case affords a good example of the manner in which the perforation is sometimes produced. This patient was seized, a few days before the accident, with acute pain in the left side of the chest; the pulse was accelerated, and other symptoms supervened, indicating an attack of pleuritis, which, being successfully combated by antiphlogistic treatment, had entirely ceased two days before the accession of the dyspnoea. From the weak state of the patient the existence of effusion could not be ascertained during life, but after death it was found to have taken place to the extent of twelve or fifteen ounces; by separating the pulmonary from the costal pleura, it had produced a partial rupture of the cellular tissue which formed the adhesion, and which was elongated between the two pleuræ to nearly an inch, and kept in a state of tension. In this state of the parts, the succussion of the cough had torn the pulmonary pleura at the edge of the adhesion, and thus produced the perforation. For this ingenious explanation of the manner in which effusion may break up adhesions, and occasionally give rise to perforation, we are indebted to Dr. Carswell."

Pneumonia, pleuritis, and pericarditis, are frequent complications of phthisis in its last stage, and often bring a case to an abrupt conclusion, which might otherwise have been protracted for several weeks, or even months.

Diseases of the Abdominal Viscera.—The gastro-enteric mucous membrane rarely escapes disease in the progress of consumption. Andral observes, that "softening of the mucous membrane of the stomach, hyperæmia of the different portions of the intestines, ulceration of the small intestine, accompanied in many instances by a development of tubercles, are all of such frequent occurrence in phthisis, that they may be fairly considered as constituent parts of the disease." The same pathologist remarks, that "these lesions may either precede or follow the formation of tubercles in the lungs; and in some cases the pulmonary and abdominal affections set in together." Dr. Clark's experience agrees in this respect with Andral's. The stomach, the lower portion of the ileum, and the colon, are the parts most frequently affected. Among the morbid conditions of the stomach there is one whose nature is not fully un-

derstood; its chief symptoms are vomiting and pain.

"Louis considers it dependent upon softening and wasting of the mucous membrane; but the experiments of Dr. Carswell have clearly demonstrated that such softening of the coats of the stomach is a *post-mortem* change produced by the action of the gastric fluid. The red softening is essentially different in its nature, and is the result of inflammation. But, whatever be the pathology of the gastric affection at present under consideration, it is very distressing to the patient, and difficult to remedy. According to the observations of Louis, it occurs from two to six months before death; but I have known it to exist for a much longer period, and even long before any symptom of pulmonary disease presented itself. In one young lady it existed for several years; and it was only within a few months of death that the pulmonary disease became evident. The extent to which the latter was found after death to have proceeded, showed how long it had remained latent, masked by the deranged condition of the stomach. Another patient, —a female, twenty-five years of age, whose brother lately died of tuberculous consumption—has retained scarcely anything on her stomach for upwards of two years, except a very little water, or toast-water; every thing else is rejected the moment it is swallowed. The emaciation and debility are very great. She presents all the external characters of tuberculous cachexia, with a short dry cough, and, if the affection of the stomach do not previously prove fatal, will most probably die of consumption at no very distant period. In this case the pain in the epigastric region is not great, even on pressure; but, in some cases, it is so severe, and so entirely absorbs the patient's feelings and attention, that, without minute observation on the part of the medical attendant, the pulmonary disease may escape notice. In general, the stomach can digest very little, and then only the lightest food. Occasionally the appetite and powers of digestion return for a time. This occurred in the patient last mentioned; during a residence in the country for several months in the summer, the stomach retained and digested light food well.

"It becomes a matter of some moment, in a practical point of view, to distinguish the vomiting which occurs in the course of consumption (and which is commonly attributed to the cough), from that which depends on a morbid state of the stomach. A little attention to the concomitant symptoms will generally enable us to make this distinction. When the vomiting is simply the consequence of the cough, we find no epigastric tenderness or pain; the appetite remains, and the digestion, in the intervals of coughing, goes on well: it frequently occurs at the commencement of the disease. When, on the other hand, it is the result of a morbid con-

dition of the stomach, it is generally preceded by loss of appetite and pain in the region of that organ—symptoms which continue and usually increase during the course of consumption: the period, also, at which vomiting first occurs in this case, is generally late in the disease.”

Enlargement of the Stomach has evidently an intimate connexion with consumption, though the cause of such connexion is not easily explained. Louis found it in more than two-thirds of the cases which he examined after death, while only two examples occurred among 230 subjects who died of other diseases: the organ sometimes acquires double or treble its natural volume, and reaches downward to a level with the spine of the pubis. *Ulcers of the intestines* are at first always small.

“They occur most frequently in the lower portion of the ileum, and chiefly in that part opposite its attachment to the mesentery, where the glandulæ agminatæ are chiefly situated. These glands form their primary seat. In the large intestines the ulcerations occur irregularly. When the ulcerative process is once established, it often extends to the surrounding tissues; the neighbouring ulcers coalesce, and the mucous membrane is undermined or destroyed to a great extent. Louis found them spreading to the length of nine inches, and running quite round the colon. Perforation of the intestine, although a very rare occurrence in consumption, occasionally takes place.

“The more early ulceration of the intestines occurs, the more rapid in general is the progress of the disease, because it is usually accompanied with intractable diarrhœa, which speedily wastes both the flesh and strength of the patient. Louis found tuberculous ulceration in the small intestines in *five-sixths* of the cases which he examined, and noticed it almost as frequently in the large intestines, the mucous membrane of which often presented other diseased appearances, being red, thickened, or softened in one-half of the cases; so that, of the whole number of phthisical cases examined by this physician, the large intestines were found in a healthy state through their whole extent in *three instances only*.”

The *mesenteric glands* are very often tuberculous, but more frequently in children than in adults; in the former they were found so by Papavoine in one-half of the cases he examined, while Louis found the proportion in adults to be something less than one-fourth.

“*Diseases of the liver*.—The liver, in phthisis, presents one remarkable alteration of structure, which consists in its

equable transformation into a fatty substance. This change appears to take place simultaneously over the whole organ, and to be intimately connected with the development of tubercles in other organs; for of forty-nine cases of this degeneration observed by Louis, forty-seven were phthisical and of two hundred and thirty subjects who died from other diseases, it occurred in nine only, seven of whom had a few tubercles in the lungs. When far advanced, it soiled the scalp and hands like common fat:—when the change existed in a less degree, its presence was detected by the impregnation of paper with fat, on a portion of the organ being enclosed in it and exposed to heat. This degeneration of the liver is marked by a pale fawn colour, diminished consistence, and increased bulk of the organ, which sometimes enlarges to double its usual size. The rapidity with which it takes place seems to depend almost entirely on the progress of consumption; for it has been found when this has run through all its stages in fifty days. Its occurrence is independent of the patient’s age or strength of constitution; sex, however, appears to have a decided influence, as of the forty-nine cases observed by Louis, only ten were males. The causes which conduce to this morbid change are very obscure: affections of the duodenum, which Broussais supposed to cause it, have been found by Louis to have no influence in its production. It is yet more remarkable that it is accompanied by no appreciable symptom except increase of bulk, and that the functions of the organ seem to go on undisturbed. The liver occasionally contains tubercles, particularly in children. A diseased state of the liver appears more frequent in some localities than in others. According to Desault, it is a very common occurrence at Bordeaux; so much so, indeed, that he scarcely met with a case of consumption in which he did not find this organ affected during life. ‘Je trouve constamment une obstruction bien marquée par dureté, et souvent douleur.’ This is certainly not the case in this country; for, although a congested state of the liver is a frequent attendant on phthisis, and often long precedes it, still I believe that it does not often proceed to such an extent as to form, during life, a perceptible tumour in the abdomen; nor is the fatty degeneration of the liver so common in this country as in France.”

Fistula in ano, having been frequently found in consumptive patients, has been thought to bear some particular relation to phthisis, but neither the observation of Andral nor of Dr. Clark has tended to confirm this opinion.

“It occasionally happens,” says our author, “that death occurs suddenly in the advanced state of the disease. The patient

does not appear worse than he has been for some days, when, while sitting up, he suddenly falls back and expires. Examination after death does not always enable us to explain this sudden cessation of life. Louis gives two cases, in one of which œdema of the glottis appeared to be the cause; and in the other, a rapid hepatization of a large portion of the lungs; but neither of these pathological lesions could account for the sudden terminations to which I allude.

"Among the causes of sudden death, *pulmonary hemorrhage* may be mentioned, as it is occasionally so profuse as to prove fatal in a few minutes. In such cases a considerable artery is opened by ulceration in the progress of the tuberculous disease."

Chapters 7, 8, and 10, treat admirably of the duration, statistical history, and causes of tubercular consumption; into these, however, our limits will not permit us to enter. We had intended to have brought this review to an end in the present number, but as we are unwilling to omit some interesting matter that remains, we must defer taking leave of Dr. Clark till our next.

—o—

Practical Observations on the Nature and Treatment of Nervous Diseases, with Remarks on the Efficacy of Strychnine in the more obstinate cases. By George Russell Mart, M.R.C.S.L., late of H. M. Ship Racoon. 12mo. pp. 185. London: Churchill. 1835.

The object of the author of this work is to detail the different diagnostic symptoms which mark the rise and progress of palsy, amaurosis, nervous indigestion, *tic dolooureux*, and neuralgia; to demonstrate the complicated nature of these diseases, and to shew that they are to be traced more frequently than has hitherto been suspected, to a morbid state of the blood, and to general constitutional disorder.

It is, in our opinion, certainly possible, but extremely improbable, that the morbid state of the blood is the cause of the disorders already enumerated.

This little work contains what may be considered new information. The virtues of strychnine are imperfectly known, and it has not, in our author's opinion, received that degree of attention which its merits demand. We entirely assent to this statement. Ample experience has convinced us, that there is not in the whole *materia medica* a more valuable remedy for nervous, spasmodic, neuralgic, and painful disorders, than strychnine. We

employ it largely, every day of our lives, in such complaints, in hospital and dispensary practice, and in the presence of several intelligent students; and also in private practice.

Mr. Mart has compressed into a small volume a very interesting clinical report of paralytic diseases, amaurosis, nervous indigestion, and neuralgia, in which cures were effected by strychnine. Though the work is written in a popular style, the facts it contains are valuable to the medical practitioner. Thus we find cases of paralysis, declared to be hopeless by eminent practitioners, which were perfectly cured by strychnine. We observe others that had passed through different hospitals, where they were declared incurable, though health was restored. We shall insert a few of the cases.

"CASE I.—In December, 1829, a friend requested the author's attendance on Mr. Wyatt, living at 45, King-street, Soho, purveyor to his late Majesty; he had palsy affecting the right side, arm, and leg; the muscles of the face were deranged, as were those of the tongue, causing him to stutter considerably. His general appearance indicated a person not in full possession of his intellects. He was unable to stand or walk, and required to be lifted into a carriage for an airing. No account of the cause of the above condition of the patient could be given, excepting fatigue and anxiety, and these of no great intensity.

"The paralytic seizure commenced three years previously, when the most eminent persons were then consulted, with little or no advantage to the patient; and as no hope of recovery could be entertained, the case was left to nature.

"The patient commenced with one-sixteenth of a grain of strychnine, in the form of a pill, taken three times a day. After two days, three pills a day, each containing one-eighth of a grain, were administered; and the medicine was gradually increased to one-third of a grain in the twenty-four hours. After continuing the strychnine for ten days, some slight twittings were experienced about the face, extending to the arm and leg. These sensations increased even to annoyance. At the end of three weeks he had more use of the arm, and could stand on his legs; and by the fifth week, could with assistance walk about the apartment.

"The strychnine was reduced to half a grain in twenty-four hours. In a few days the expression of the face became altered; from a silly look it changed to one expressive of archness, brightened by a good-natured smile. At the expiration of seven

weeks he walked without assistance. As he improved daily, and had been under treatment ten weeks, the medicine, about the end of February, 1830, was discontinued. He was visited again at the commencement of April, when he walked about the house, and expressed a hope to be soon able to ride out. In May, four months after the treatment had been commenced, he was able to proceed with his customary occupations; and about the same time he gratified the author's friend by driving to his residence.

"In July, 1832, Mr. Wyatt, now living in the Edgeware Road, was observed by his family to be labouring under unpleasant symptoms. Very soon afterwards he had an *apoplectic* seizure, and continued in a state of insensibility *fifty-eight* hours. During the fit, he was once seen by Mr. Copeland Hutchinson, of Duchess-street.

"Active treatment was used, consisting of general and local bleeding, *ice* to the head, warmth to the feet. The introduction of a catheter was required.

"Palsy of the right side was observable after the apoplexy went off, but in about three months the use of the limbs returned. The strychnine was again administered, conjoined with other remedies. Four months had hardly elapsed before he accomplished a walk to town, a distance of three miles. He is now in good health, and is able to take a very considerable degree of exercise daily.

"The result of this case excited surprise among the patient's family and friends; who viewed him as a person afflicted with a disease which would endure with his life, and in this view were confirmed by the opinion of others. It also strongly points out the efficacy of strychnine in a *long-neglected* and hopeless case.

"The recurrence of the apoplectic attack, two years after the palsy had been cured, probably had no relation with the former complaints. A fit terminating favourably, after enduring *fifty-eight* hours, is not of ordinary occurrence. The loss of motion of one side was complete. Nevertheless, the patient, by the use of the strychnine, recovered the power of the arm, and of locomotion in four months, while in the first attack he had been for *three years* unable even to stand.

"When palsy seizes persons of a strong and plethoric habit, it is attended with considerable disturbance of the functions of the brain, either previously to or during the attack; this derangement varies from forgetfulness, of a minute's duration, to that state of insensibility which characterizes a fit of apoplexy.

"It also happens with some paralytic patients, that whenever the circulating system becomes overloaded with blood, or the nervous system much excited, *epileptic* fits occur, which aggravate the condition of the

patient. In some instances, these appear at intervals of a few days or weeks, while in others they extend to two or three months."

After some judicious remarks on the pathology of paraplegia, in which much stress is laid on the fact, that disease in the brain is the cause of some forms of this species of palsy, a remarkable case is related in which strychnine effected a cure.

"CASE VII.—Thomas Linton, aged 42, had been two years in the Racoon Hospital Ship, in Portsmouth harbour, before the date of the author's appointment thereto. He was tall, thin, and had a sallow complexion, and was the most intelligent patient in the ward. He stated that he had not quitted his bed for twenty months, except on favourable days, when he was carried on deck for fresh air. The cause of the palsy was a blow on the loins by a fragment of stone, attended with considerable pain at the time, which in a day or two passed off. Some time afterwards he became alarmed by a feeling of numbness extending along the thigh, and a sensation as though strings were tightly bound round the legs. These symptoms increased, and at the end of three weeks the man was deprived of motion of the legs, and became unable to stand. Every means of cure were tried, including a mercurial course, which caused a loss of several teeth. Poor Linton received no advantage, and was considered 'an incurable.'

"The treatment was commenced by administering some blue-pill, and doses of purgative medicines; the state of the secretions required previous treatment. Afterwards, one-eighth of a grain of strychnine was ordered in the form of a pill twice a day, and a dose of a mixture containing *diluted sulphuric acid* taken at the same time. On the second day the pill was repeated three times, and the strychnine was gradually increased to a grain in twenty-four hours. When the treatment had been continued a month, no amendment occurred; but about this time a blister was applied over the part where the blow was received. On removal of the skin, one-quarter of a grain of strychnine was applied twice a day. The blister was dressed daily in this manner till it healed, when another was applied in the vicinity, which was dressed with half a grain of strychnine sprinkled over the denuded surface twice a day, and also administered internally in pills containing a quarter of a grain four times a day. Six weeks from the commencement, the patient began to improve; convulsive jerks were felt in the legs, and a sense of pricking and other odd sensations were experienced: the toes would move involuntarily. An erect posture had been attained several days; the patient sat in a chair, and moved the legs in every direction. He continued to improve in various degrees;

but the amendment was always more rapid after blistering. This treatment was continued four months; when he was so far recovered as to be discharged from the Hospital Ship, and had light work assigned him. Finally the cure became perfect, and he performed the duties of an able-bodied man."

Under the head "amaurotic blindness," are cases in which vision was restored under very unfavourable circumstances. We shall cite two of them.

"CASE XIII.—Fryer (an account of whose palsy of the limbs is related at Section I.) had amaurotic blindness affecting both eyes. When in a room he could only distinguish the aperture through which the light entered. He knew no one by sight, nor could distinguish the sex of individuals as they passed him. This very imperfect state of vision was produced by an attack of apoplexy occurring subsequently to the paralytic seizure. It will be recollected that this patient had epileptic fits every four weeks. The eyes had a wild staring look; but both were not equally affected.

"He was under treatment for eight months, and was twelve times blistered about the outer angle of the eyes, and over the brows, the blisters being about an inch in diameter; but he felt no inconvenience from them. Having undergone such rigorous treatment at Hospitals, he cared not for trifles.

"The restoration of vision was effected gradually. Many weeks elapsed before the slightest improvement was detected. In bright sunny days he could define passing objects, as various shapes of carriages, colour of horses, articles of dress, could then recognize friends, and examine the contents of street bills. When last examined he detected a fly creeping on the window.

"His state of vision always was aggravated some days previously to an attack of epilepsy—these fits have now disappeared. The sight continued to improve for a long period after discontinuing the treatment. He is of a full plethoric habit, and occasionally loses blood by cupping.

"CASE XIV.—Mr. D—y, a gentleman, living at the end of Harley Street, New Road, has been afflicted with amaurotic blindness many years. The deprivation of sight was sudden, both eyes being affected. The patient can scarcely distinguish the outlines of a human person, and requires a strong light even to perceive a white object on a dark ground. He experienced at times much inconvenience in standing and walking, and occasionally was unable to do either without support. During these attacks of nervous debility in the lower extremities, and whenever great atmospherical vicissitudes occurred, he was seized by neuralgic pains at various parts, frequently preventing sleep at night, and causing much disquietude through the day. The pains were sudden

and transient, returning at intervals of ten or twenty minutes. The principal seats of pain were the legs and sometimes the arms.

"This case has been seen and treated by the most eminent medical practitioners; no means being spared for advice, which was eagerly sought for wherever there was a chance of deriving benefit.

"Treatment by strychnine was used for three months, internally and externally; blisters were applied to the nape of the neck, and also about the eyes, and dressed with strychnine after the cuticle was removed. The pills were given with one-tenth of a grain in each, and gradually increased to one-eighth and one-sixth three times a day.

"The result of the treatment was decided benefit in walking and standing, so that the patient could walk round Regent's Park; the pain along the nerves of the legs and arms ceased, leaving a dull, uneasy feeling, analogous to slight rheumatic pains.

"There was a probability of more advantage being derived had the treatment been carried on a longer period. A few days previously to the medicine being discontinued, the patient was in a chair at the dinner table, and on looking round was amazed at beholding distinctly many features which he had been unable to distinguish for years past. The eyes, shape of the nose, and the teeth of the company were perceived. This improved power of vision continued nearly all dinner time; it then fell back into the old condition, and has remained so to the present hour. A further trial of the treatment was unfortunately never given, although it would warrant a repetition."

After a graphic description of nervous indigestion, in which patients complain *de omnibus rebus et quibusdam aliis*, a case is related which deserves attentive perusal.

"CASE XVIII.—Miss Cook, of Edinburgh, aged 35, had come to town for advice, and was living in the Adelphi Buildings. She had from the age of fourteen been afflicted with headaches. At first they were ascribed to irregularity of the salutiferous periods; then to disturbed functions of the stomach, to diseased liver, to a renal complaint, and latterly to an undefined chronic affection of the membranes of the brain. For these several maladies she had been under treatment.

"Her head at length became the principal seat of complaint. On rising in the morning, and at various periods of the day, the patient would foretell the approach of an attack, by a coldness creeping over the body, by numbness of the scalp—especially over the forehead, by dimness of vision, and by a disposition to vertigo—accompanied by nausea, and sometimes by vomiting. Pain in the head would then commence, and increase in intensity, till, from severe suffering, she was compelled to retire to bed in a state

of stupor. At these times the senses of sight and hearing were so painfully acute, that she could neither endure the presence of light, nor the sound of the voice. A bandage tightly bound round the head, restrained the beatings of the blood-vessels. After suffering in this manner from six to eighteen hours, the patient would then obtain sleep, and waken free from pain, but weak, pale, and emaciated. The simplest variation from regular habits, such as a drive in a carriage, a sudden alarm, unexpected intelligence, a quick walk, or any sudden call for exertion, has produced the attacks. When free from headache, her temper was cheerful and lively, though she daily experienced some of the symptoms which characterize gastric nervous irritation; such as sour eructations, flatulency, heartburn, and occasionally *water-brash*, which is a discharge of a clear insipid liquid from the stomach.

"The disordered secretions had been corrected by alterative medicines, and some leeches applied to the back of the neck to relieve the congestion supposed to exist in the head. The health was moreover generally improved by proper diet and exercise. The patient began the treatment by taking one-tenth of a grain of the sulphate of strychnine, in the form of a pill, night and morning for three days. Afterwards, three pills were taken every day for eight weeks.

"Ten grains of strychnine were dissolved in five ounces of spirit, half an ounce of which was rubbed on the back of the neck every night. An attack of headache occurred a week after the treatment was commenced, but there was no return of it during the remainder of the time the medicine was being administered. Previously to this, the attacks generally appeared at intervals of ten or fourteen days. After the treatment was discontinued, a dull pain was felt at the forehead every morning on rising, and continued one or two hours after breakfast. This symptom finally yielded to the cold shower bath."

We can bear our testimony in favour of the great value of strychnine in similar cases, and order it in the dose of one twelfth of a grain in a pill twice a day, for at least a dozen patients daily, in public and private practice.

The last part of the work before us is devoted to the pathology and treatment of neuralgia. In this section are some cases which will be perused with instruction, and these were cured by strychnine.

In conclusion we have to remark that this little work is well executed, and contains much interesting information. It will no doubt contribute to induce practitioners to

employ one of the most powerful and valuable remedies we possess. We wish others would follow the example of Mr. Mart in giving much practical information in the shortest possible space. The work reflects much credit on the author, and proves him to possess great skill in the distressing diseases of which he has treated.

The London Medical

AND

Surgical Journal.

Saturday, August 29th, 1835.

ONE FACULTY—REAL REFORM MUST BE THE WORK OF THE PROFESSION ITSELF.

We have good grounds for hoping that the one medical faculty so ardently desired by all enlightened members of the profession, and so vehemently declaimed against as absurd and impossible by the corruptionists, will ere long be actually established—that it must be so eventually we never entertained a doubt. Only a little while ago we were laughed at as visionaries by some, and regarded as simply insane by others, for our opinions on this subject; it was matter of astonishment that grave men like ourselves should be led astray by an ignis fatuus generated in the overheated brain of Mr. Wakley; but the fact is, we were precisely of the same opinion long before we ever heard of that gentlemen; and, strange to say, many who formerly pitied his and our delusion, have now become converts to the doctrine—the rest will, perhaps, like Thomas, believe when they see. The establishment of one faculty, however, will only lay the foundation of efficient medical reform; such reform cannot be perfected by the legislature, but must be the work of the profession itself. There are evils to be eradicated which legislation cannot reach, and improvements required which can only be brought about by a good internal organization of the profession, springing from liberal feeling and gentlemanly

conduct on the part of its members. Among the evils to be eradicated, the principal are, the dispensing of drugs by medical practitioners, and gratuitous attendance at public charities. On both of these we trust enough has been said by us on former occasions to convince all unprejudiced persons of their degrading and injurious influence on the profession; but it is not in the power of parliament to abolish either of them by any direct enactment. It would be to the last degree arbitrary and unjust, immediately to inhibit all medical practitioners from dispensing drugs, because there are many most respectable members of the profession who depend for their subsistence mainly on their retail shops; all that the legislature can do is to place the practitioner in a condition to be independent of trade, if he pleases, by entitling him to a fee for his attendance; the evil can only be entirely abolished by the influence of professional feeling and opinion, which have always great weight, where a learned fraternity is properly constituted: it is true, indeed, that the opinion of the profession at present goes for little or nothing with its individual members—but why? Because it is in reality not worthy of regard; the profession is a mere name; it has no united opinion—no moral influence—no collective respectability.

Again, parliament cannot prevent medical men from offering their services gratuitously to hospitals and dispensaries; but the profession itself might gradually abolish the practice, by attaching the merited stigma of hypocrisy and self-debasement to the man who used charity as a cloak for his own private views, or who submitted to be made a drudge and hack in the hope of future emolument.

Among the improvements for which the institution of one faculty will afford scope, but which it rests with the profession itself to effect, the most prominent are the establishment of a sound

code of professional morality, and the extension of the means of scientific instruction. Medical ethics is at present a term without a meaning; relative duties can neither be understood nor fulfilled unless the relations which entail them be determined; but as the profession is now constituted, no man can distinctly comprehend the relation in which he stands to his neighbour; hence it is not wonderful that each should interpret it in the manner most favourable to himself, and that the maxim “catch who can” has come to be regarded as a compendium of medical morality: thus the duty of the general practitioner is to keep the physician out as long as possible, and that of the physician to oust the general practitioner whenever he is able; the duty of a pure surgeon is to proclaim the necessity of an exclusive addiction to *surgery*, and to take all the *medical* cases he can get; the pure apothecary affords an amiable exception to this selfish rule; his duty is to cultivate the “good understanding” system at the expense of the patient, and to call in his friendly physician or surgeon whenever physic goes further than a catarrh, or surgery deeper than a cut finger; a reciprocity of *pure* feeling towards himself is indicated by a prescribed transfusion of the whole contents of his shop into the stomach of the patient. Such ethics as these might possibly be improved under the auspices of one faculty, where the same temptations to evil would not exist; where the recognised relations of medical men to their patients would be those of skill and humanity, and their relations to each other those of honesty, with a due admixture of courtesy in both instances. Under such a system every member of the profession would feel himself in some degree amenable to the opinion of a large body of men whom similarity of education and objects rendered the best judges of his proceedings; the charge of “unprofessional conduct”

might then be a grave one, instead of being, as it now frequently is, a mere indication that the individual has acted according to the dictates of common sense.

Again, under one faculty, the opportunities of scientific improvement might be infinitely extended. A museum and library open at all reasonable hours, lectures delivered by able professors on every branch of medical science, and meetings of the faculty for the purposes of mutual instruction and consultation on the means of promoting professional improvement, would speedily change the aspect of British medicine, and enable us to convince the world that, with equal advantages, England yields not to any country on earth in the will or the power to advance this noblest of sciences. If we have been more ready than may have been agreeable to the prejudices of some of our contemporaries, to acknowledge our present inferiority, none will be prouder than ourselves to record the rapid progress which we feel confident will result from the dissipation of the thick cloud of barbarism which has hitherto brooded over the scientific institutions, and damped the scientific ardour of our country.

Hospital Reports.

WESTMINSTER HOSPITAL.

Cases illustrative of the benefit to be derived from the use of the Balsam of Peru, as a local application, in Sloughing and Phagedænic Ulceration of the Genital Organs.

Sloughing Ulcer of the Prepuce, terminating in the total destruction of the Glans.

EDWARD HERRING, aged twenty-three, was admitted into Burdett Ward, July 14th, under the care of Mr. White. He has had a small sore on the outer surface of the prepuce, during the last two or three months, which attracted very little of his attention; it spread slowly, and attained a size about equal to that of a sixpence, being somewhat of a circular form. He merely took a few pills and salts for it, and does not appear to have regarded it as venereal.

On the Monday week previous to his admission he got intoxicated, and from this period it began to spread, and to assume an unhealthy character. At the present time the penis is swollen to a considerable extent, has a glabrous character, and is pervaded by a deep erythematous blush, except about the glans and prepuce, where the ulceration exists, and which possess the flabby, dark, and moist character of gangrene. No limitation appears at present to be set to this destructive process. The tongue is slightly furred with red margins, appetite is much impaired, bowels are regularly open, pulse 96, hard and thrilling. Mr. Thomson, who saw the case for Mr. White, directed lint dipped in Peruvian balsam to be applied to the ulcerated and gangrenous parts, and the entire penis to be afterwards enveloped in a warm poultice. The following mixture was likewise prescribed:

℞. Quininæ sulphat., gr. viij;
Acid. sulph. dilut., ʒ ij;
Decoct. cinchonæ, ʒ viij;

M. Capt. cochl. ij ter quotidie.

17th.—Seems rather better; the penis, however, remains in much the same condition, except that the gangrene appears now to be limited about an inch above the prepuce. He does not complain of much pain, and evacuates the bladder without difficulty. The tongue is very flabby and moist, and covered with a thick fur; the appetite is something better and the bowels open; pulse 96, and of the same thrilling character as before.

18th.—The gangrene appears now to be completely checked, but the inflammation in the penis, especially about the line of demarcation, is still very active. The pulse, both as regards frequency and other characters, is the same as at last report. He continues the application of the Peruvian balsam and the poultice.

20th.—Is a great deal better; the inflammation in the penis is abating, and the separation of the slough has commenced. He has now no pain at all. The tongue is less furred; pulse 84, and not of so irritable a character.

21st.—The greater part of the slough has come away, and has left a healthy-looking, granulating surface, which secretes a laudable pus. The inflammatory action in the penis is likewise subsiding. The appetite is better, and the general health in all respects, appears to be improving.

23rd.—A progressive improvement appears to be going on.

25th.—The whole of the slough has come away, and has left a sore having a very healthy character, and granulating nicely. The whole of the glans and prepuce, however, as well as a portion of the body of the penis have been lost.

28th.—Going on favourably, both as respects the local and constitutional conditions.

30th.—During the last week he has become very deaf, and has had a discharge from both ears.

August 8th.—The deafness and otorrhœa have both now ceased. The sore on the penis is now about cicatrizing. At the extremity of the penis is a small roundish tubercle, which is surrounded by a circular fold, the two resembling a rudimentary glans and prepuce.

Phagedænic Ulceration of the Penis, rapidly destroying the Prepuce, Glans, and a considerable portion of the entegument of the Penis.

James Havell, aged nineteen, was admitted July 19, into Burdett Ward, under the care of Mr. Guthrie. He appears to be of dissolute habits, and of a broken-down constitution. His occupation is that of selling fruit in the streets, and his residence is in one of the lowest parts of Westminster. On Monday week, the 10th instant, he first noticed a small sore, about the size of a pea, on the inner skin of the prepuce. This was about three weeks subsequent to the last time of his having venereal connexion, in the indiscriminate use of which, however, he had frequently indulged during the preceding month. He neglected to apply any where for advice until Thursday the 14th, when finding that the sore was making progress, he became an out-patient at the hospital.

Mr. Soden, the house-surgeon, ordered him the black-wash, as a local application, and the blue-pill, in five-grain doses, three times daily. Under this plan, however, the sore continued to spread, and the patient perceiving a small black spot on the outer skin of the prepuce, applied a poultice over it, after which there was a complete perforation of the prepuce. The sore now rapidly spread, assuming an unhealthy, corroding-like character, destroying a considerable portion of the prepuce and extending likewise to the glans. So rapid was it in its ravages, that between Thursday the 14th, and Monday the 18th, the half of the prepuce, and a great portion of the glans were destroyed by the ulcerative process. During this period, he had been leading a very irregular life, drinking at least four or five, and sometimes seven or eight pints of beer daily, as he says is his usual habit. He was taken into the hospital, on the next admission day, as above stated. At this time the prepuce, on the left side, is entirely destroyed, as well as a portion of the glans and skin of the penis, so that the corpus cavernosum is exposed; the whole sore has a highly irritable and offensive aspect. The body of the penis is extensively swollen, and of a deep red hue, as though from phlegmonous erysipelas. Mr. Thomson, who was acting for Mr. Guthrie, made an incision, about an inch in length, into the most swollen part of the organ; the

mercurial plan of treatment was ordered to be discontinued; the Peruvian balsam dressings and poultice were directed to be applied, and he is to have the following mixture—

R. Extracti sarsaparillæ, ʒj;
Decot. sarsap. comp, Oj. M.

Fiat mistura, capt. part. tert. ter. quotidie.

He is ordered fish diet, and to keep constantly in bed.

23rd.—Under the above treatment, the sore has already put on a more healthy character, and the progress of the ulceration appears to be checked. The penis is less swollen and red, and in every respect he appears better. He continues the remedies.

28th.—Going on well; the sore has now a very healthy character, and is granulating favourably. His general health appears pretty good.

30th.—Continues to improve rapidly; the inflammation in the penis has almost entirely subsided, and the ulcer has nearly filled up with healthy granulations, the sore, appearing disposed to heal quickly. It is now dressed with pledgets of simple cerate. He only takes the sarsaparilla, and an occasional aperient.

August 1st.—The sore is now rapidly healing, and has commenced to cicatrize. His general health has very much improved.

Although the case reported last week is not of the same description as the foregoing, yet as it possesses some affinity to them, and was benefitted by a similar plan of treatment, we applied it to them.

Hydrophobia.

August 21, 1835. — Chester, aged 72, a powerful muscular man of his age, was admitted into the Westminster Hospital at half-past one to-day, under the care of Dr. Burne; only an imperfect history of the case could be obtained. About fifteen months back, he was bitten by a dog on the fore-finger of the right hand, from which he has from time to time suffered some inconvenience, and applied to a neighbouring chymist for relief. He had been poorly some days back, and yesterday morning, vomited his breakfast, which he had just taken. Since then he has been complaining of a sense of constriction about the throat; the bowels were freely purged yesterday; also this morning, he has had two doses of the acetate of morphia of $\frac{1}{4}$ grains of each. At the time he was brought to the hospital, he was in the following state: the cicatrix of the bite was apparent, and the hand rather swelled and inflamed; a blue line, probably an inflamed lymphatic, extending from the cicatrix to the elbow was visible; pulse 54, occasionally irregular and unequal;

tongue red; great desire to eat and drink, but unable, except a small quantity of fluid, and that with considerable effort. There is a great inclination to vomit, but he brings up nothing.

At half-past four he has had one drop of hydrocyanic acid, and also a few tea spoonsful of liquid; the pulse has varied from 45 to 60; the inclination and efforts to vomit are greater; respiration frequent, and varying much numerically; countenance anxious, but spirits excellent; abdomen tympanitic; convulsive spasm of the throat comes on occasionally, with suffocating cough on the approach of air or liquids, and at intervals, without any apparent exciting cause, when there is slight horrifications. At the approach of liquids, he eyes them, perhaps, even professes a desire for them, from thirst, but appears to have an uncontrollable, unconscious aversion; but neither on this point nor on the approach of air is he as morbidly sensible as the boy who was in Charing Cross Hospital some time back. He was ordered ext. bellad. $\frac{1}{4}$ grain to be taken every hour in some soft vehicle, so that he might suck it.

At half-past eight a great change has taken place; the pulse, at half-past four about 52, has rapidly risen to 160; it is a moderate size, open, and yielding, but still perfectly distinct. A blister has been applied to the neck, with the view of applying some anodyne endermically. He is much excited, and talks rather incoherently, but a rational answer can be obtained without difficulty. The exhibition of a looking-glass does not affect him. Blowing upon him pretty strongly convulses and makes him shudder.

At a quarter-past nine, he has passed urine which is scanty and high-coloured. The hawking and gulping, and suffocating cough recur more frequently. He has taken three doses of belladonna. The only thing he complains of is a sense of constriction across the chest. When asked to drink, he says he "should like it, but not just at present, as it would throw him into a perspiration." He put his hand into water rather reluctantly, but quickly withdrew it, and wiped it. Before each convulsive paroxysm, there is a great deal of hawking. The eyes have rather a glaring expression, and the countenance has become more anxious, but he does not appear to have the slightest apprehension of any danger. The excitement soon became greater; his wish to walk about the room a little was indulged, but he became so outrageous that the assistance of several people was necessary to replace and keep him in his bed. After a consultation between the medical officers, when some doubt was expressed as to the identity of the case, especially by Mr. Thomson, it was resolved to administer an injection containing three grains of elaterium immediately, to be followed with others, containing two grains of

the extract of belladonna each, according to circumstances.

At ten, face much suffused, eye-balls tremulous, pupils much dilated, cough more frequent, and he blows violently from his mouth; pulse about 190, perfectly distinct, small, and soft.

At half-past ten, the enema has not operated; another was administered, consisting of ext. belladon. gr. ii; jusculi bov., $\frac{3}{4}$ iv; amyli, $\frac{3}{4}$ ss; he coughs and gulps more frequently, but is much more tranquil.

At a quarter to eleven, he does not now appear sensible, nor can any answer be obtained from him. He is now quiet as to active exertion, but there are frequent convulsive movements, moaning, hawking, and rattling in the throat; the feet are getting cold, but the head is excessively hot; the pulse 145, rather full, soft, and compressible; bowels not open. He has thrown up a small quantity of frothy coffee-coloured fluid.

At a quarter past eleven, pulse 144, smaller, but quite distinct; exhaustion greater, eyes glassy; countenance livid; moves but little; suddenly he became more tranquil, the cough and gulping ceasing, and in five minutes he was dead.

Autopsy twelve hours after Death.

The muscles and joints of the lower extremities were stiff; those of the upper flaccid. The posterior part of the body, and the entire head were livid, especially towards the right side. The abdomen was rather tympanitic. The scalp was gorged with blood, and on removing the calvarium, a large quantity of black blood escaped from one of the sinuses, which was wounded. The blood in all the veins was black and fluid. The brain was rather vascular. The cerebral ventricles contained about $\frac{3}{4}$ liij of fluid, and their veins were rather congested. There was a good deal of venous vascularity. About the substance of the brain, the organs of the nerves presented no unnatural appearance. The laryngeal and tracheal lining membrane was excessively injected, but quite sound; the same state extending down to the lungs, which were uncollapsed, and full of frothy mucus, presenting on their surface many purplish red spots. There was very great vascularity of the pharynx, uvula, velum, palati, pillars of the glottis, surface of the tongue, and epiglottis, diminishing towards the pharynx, and increasing towards the larynx. The stomach was perfectly healthy, and the intestines moderately inflated.

Dr. Burne considered this a true hydrophobic case, and declared his intention of making it the subject of a clinical lecture in the course of next week.

THE MEDICAL PROFESSION AS IT IS,
AND AS IT OUGHT TO BE.

*Mr. Dermott's third Letter to G. J. Guthrie,
Esq.*

DEAR SIR—My last letter related to the merits, more particularly of private lecturers, improperly so called, and to objections advanced against any persons, not hospital surgeons, teaching anatomy.

We next proceed to your objections against permitting any young men to become examiners in the College of Surgeons.

You do not admit that the younger men in the profession (say from 25 to 35 years of age) are competent to be examiners, not until they are at least 40 years old, because, you state, they are before that time only theoretically acquainted with the profession.

Now, the same observations which I made in my last letter, as to the competency of a lecturer, will apply, in the fullest extent, to that of an examiner; it is not merely your own experience, but also the experience of others, which makes you so competent an operator, a lecturer, a general practitioner*, and an examiner; take away your theoretical knowledge, and where would even you be left.

If the principle be once admitted, as it has been practically by the College, again and again (both in hospitals and out of them), that young men at 25 years of age can efficiently teach anatomy, then are they also competent to be examiners; for I hold that a man must be competent to examine upon that which he can preach about. This applies to the pulpit, the bar, and to all arts and sciences.

In reference to the incompetency of persons to fill the office of examiners, it must be observed, that, as a general rule, very old persons are, of all others, most incompetent either to examine or lecture; for a person to be either one or the other, he should possess a clear and quick perception, good memory, a collected mind, and firm nerves—not the semi-paralyzed brain of dotage.

It is true we, have as a singular exception to this general rule, Sir William Blizard, who still retains his natural vigour of mind, and even body, and who is, notwithstanding all that may have been said against him in some quarters, the best examiner at the College, the fear of whose examination produces a more salutary effect in stimulating the pupils to study, than anything besides connected with those examinations. It is true that in the Board of Examiners, or about to become some of that Board, we chance to have a Cooper, justly termed a Leviathan in

surgical knowledge, a Brodie, a Lawrence, and a White, the latter characterised for his surgical judgment, and his fatherly attention to his pupils; and that we have also had a Lynn, who was declared by John Hunter to be, during his time, the best operating surgeon in London. But it is also true that others have been chosen, who have neither been distinguished “for their high moral character” (witness the burning of the Hunterian manuscripts), nor for their “considerable attainments in anatomy, physiology, and surgery, and the higher branches of the profession.”

The younger examiners are generally the most “sifting.” Old men, on the other hand, get doting—they dote on persons, dote on things, dote on words, whilst their prejudice in favour of certain opinions (and it must be the fate of us all, if we live to be old), increases with their years; hence some of the elderly examiners have had a certain routine of questions from which they have seldom or never deviated, and which are well known both to teachers and pupils.

In order to show exactly how the choice of examiners had been conducted for the last fifty years, a list not only of those who had filled the office during that time should have been called for, but also of all those *who have been passed over* by the College during the same period, and the grounds of objection advanced at the time of balloting, against their admission distinctly stated. This would have been but fair, as well as possible, as I suppose minutes are kept of those meetings.

In addition to your proposal, that the mode of election should remain as it now is, two other plans were brought forward—the first, Mr. Lawrence's, that the electors should be those who practise surgery only, and which would be a base injustice to general practitioners, not to be tolerated in the present age of reason, and ill accorded with his professed opinions in 1826. The second, Mr. Travers's, Sir A. Cooper's, and others, *that there should be two grades, a superior and inferior*; the latter to comprehend the general practitioner; but for the superior grade, they propose a man to be highly versed in various languages, to produce certificates of having attended a vast number of courses of lectures on the various sciences, medical and non-medical, and having pursued a formal and most expensive routine of study for several years; that the successful candidates should acquire the name of “Bachelors of Surgery;” and that out of this body (about they compute, 50 or 100), the examiners, the teachers, and the council should be chosen, by the council itself. I presume this would form an aristocratic body, and the corporation would be nearly as close as at present, for these bachelors would be often brought in contact with their seniors in the council—would be in surveillance to them, inasmuch

* By general practitioner I mean the man who treats both medical and surgical cases: we are all general practitioners.

as they would naturally look to them for preferment as to appointments, and for patronage in practice. Besides, the plan would be a perversion of nature itself; for, as I stated in my evidence, after a man, possessing natural talent or genius, has made such an advance in preliminary education, and the general knowledge of his profession, as to guarantee him worthy of being trusted with the lives of the community, his mind adopts a course of thinking for itself, and he pursues a particular branch of his profession, perhaps to the almost total neglect of other sciences. This is the character of true genius. His pursuit may be physic, or morbid and healthy anatomy, or surgery.

In corroboration of this, most of the great discoverers have been very ignorant in some of the leading sciences, and perhaps knew nothing of foreign languages. It would, therefore, be thwarting the course of genius to insist upon a man's proficiency in many languages and sciences, for the purpose of his attaining the higher grade. When a man's attention is divided between many sciences and languages, he improves none of them; and he seldom excels in any. In place of these two regular grades, I should propose, that after he has taken his license out as a general practitioner, to become a consulting physician, he should be obliged to undergo a suitable, severe, and public examination in sciences connected with physic; or, to become a consulting surgeon, a suitable severe examination in branches connected with surgery; and this seems to accord with Sir B. Brodie's view of the matter.

In reference to the two proposed grades, Sir C. Bell says, that "the plan would be attended with great difficulties and disadvantages: industrious men of moderate fortune could not gain an admittance into the higher grade; and a man who has to struggle against difficulties, acquires greater strength of mind, and is the greater proficient; crowding the curriculum as to the requisite number of courses, &c., is always disadvantageous." Thus, then, the grade itself would be a political, aristocratic body (as you yourself stated), confined to those of property, to the detriment of the poorer and really industrious; besides, who, as the council of the College is now constituted, is capable to decide the competency of a candidate for this proposed batchelorship. Are you, or the majority of the best surgeons of the day, competent to examine or be examined on medicine, on the dead languages, on the various branches of natural philosophy, as well as on the abstruse theories of the present day in physiology, pathology, and surgery? Why require more from these new candidates than you can do, or are expected to possess yourselves. It is absurd to expect a man to shine as a deeply learned scholar in all the various branches of the medical profession, both as physician and surgeon, in natural

philosophy, and classics too. Again, calling in others, (whether physicians, classical scholars, or natural philosophers), to aid you in the examination of candidates for the higher grade, would be a confession of weakness most humiliating on the part of the council; for you would be saying to the public, in effect this—we consider it absolutely necessary for this gentleman to be deeply learned in all these branches of human knowledge, before we admit him on a level with ourselves into the higher classes of the profession; but we are obliged to call in the aid of others to assist us, inasmuch as we are quite incompetent, *individually*, to undergo or conduct the examination ourselves. There would be, by these two grades, a macadamised path open for favouritism. The right of being examined for the higher grade would depend, for the most part, on certificates, which have too often been a farce at best, both in the hands of hospital surgeons and others; they are tests that the pupil has, probably, a pocket full of money, a mind full of indolence, and a head full of ignorance.

In anticipation of future changes, an immense number of empirics are attempting to obtain diplomas, directly or insidiously, from any chartered medical corporation that they can; and by favouritism, or any means that they can possibly devise. Let the College look well to this; for the public eye is now upon them. Let them be heedful of their conduct with regard to the E—d—s, the I—d—s, and many others of the same cast, although, perhaps, not quite such glaring offenders. But there are many practitioners who commenced before the year 1815, who never attended a single lecture, nor, perhaps, read a medical journal, and who are trespassing upon the public without having undergone any examination, or gained any diploma whatever.

I remain, yours, obediently,
G. D. DERMOTT.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXVII.

Phænomena of Motion.

WE have now to return to the proper motiferous nerves, and the motiferous portions of the regular nerves, in conjunction with a department of some of the respiratory nerves, which, like the facial and pneumogastric, are furnished with motiferous filaments, as the channel by which this intermediate irritation of the anterior columns of the spinal cord is translated to the voluntary muscles, so as to act as a stimulus on their irritability. The chief circumstance tending to prove that this is their office may be shortly spoken of in an order similar to that in which those were described which render it probable that the office of the respiratory nerves is to convey the stimulus of sympathy and passion or instinct. These circumstances were connected, 1, with their distribution; 2, with their association with other nerves; 3, with their dependence on the action of the brain; 4, with their development in the various tribes of animals; 5, with their structure; 6, with their competency to conduct certain artificial stimuli; 7, with the phenomena resulting from the irritation; and, 8, with the phenomena resulting from their obstruction (*a*).

(*a*) The proper motiferous nerves enumerated in the tabular view of the nerves of the human body, already presented, consist of the motor oculi, a part of the lower maxillary branch of the trigeminus, the abductor and the hypo-glossal, and the regular nerves—one portion of each of which is also motiferous—of the sub-occipital, the seven cervical, the twelve dorsal, the five lumbar, and the five sacral. To these must be added, as elsewhere explained, a portion of the facial nerve as well as of the pneumogastric; the other respiratory nerves, although most of them have been looked upon at one time or other as motiferous, being, if at all, certainly very obscurely connected with the system in question. All the proper motiferous and regular nerves have been pretty generally admitted, from a very early period, as performing the office above ascribed to them, except the motiferous portion of the lower maxillary branch of the trigeminus, which was first distinctly described as such by Mr. Mayo, Sir Charles Bell having erroneously represented the whole of the trigeminus nerve as a regular one—that is to say, as both motiferous and sensiferous in all its branches—whereas, it is now known

that, as the ophthalmic and upper maxillary branches of this nerve, together with the larger portion of the lower maxillary branch also, are exclusively sensiferous, the smaller portion of the last is equally exclusively motiferous. It is a very common, but a very erroneous impression, that the ancient physiologists were quite ignorant of the plurality of the nervous system, and, ascribing as they did, merely the power of exciting voluntary motion, and of communicating sensation to these agents, attributed these offices conjointly and indiscriminately to all the nerves with which they were acquainted. So far, however, is this from being the case, that even Herophilus and Erasistratus—the first to dissect a human body—were accustomed to distinguish the *Νευροὶ κινητικοὶ* from the *Νευροὶ αἰσθητικοὶ*; and Galen expressly says that all the hard nerves belong to the former set, and all the soft ones to the latter. (De Administrat. Anatom. Lib. iii, c. 17; De Usu partium, Lib. viii, c. 16, &c.); a statement which, with a very little alteration, would strictly correspond with the fact. The same doctrine was inculcated by Aretæus (De Paralysi) Ruffus (De Appel. Part.), and other ancient authors,

I.—With respect to the distribution of the proper motiferous and regular nerves, this is found to correspond very accurately with the presumption that it is these systems which communicate the stimulus to voluntary motion—such organs as are not amenable to this stimulus having no obvious supply of nerves from these systems, while those which either occasionally or habitually obey it derive their nerves either partially or principally from these sources. All the nerves conveying this stimulus appear to arrive from the two anterior columns of the spinal cord, the proper motiferous having no other origin, but the regular having a second root from the posterior columns, in virtue of which they conduce, not only to voluntary motion, but to sensation also (*a*); and these nerves, extensive as is the collective area over which they are distributed, are nevertheless less generally disseminated than the respiratory nerves, in proportion to the less extensive sphere of their operation. Thus, no such nerves appear to be distributed to the heart, the various secretory organs, the stomach, the iris (*b*), or any other parts over the motions of which we exercise no control; whereas they are found to supply, in common with obvious branches from the respiratory system, the respiratory muscles, and all those by which the numerous motions connected with this process are effected, those by which the aliment is received and transmitted to the pharynx, those which minister to the excretion of the stools and urine, those by which copulation is performed, and those which conduce to certain movements of the nostrils, eyes, face, and other organs commonly excited by sympathy and passion or instinct, but capable of being effected, as well as liable to be continually modified by volition; while it is, lastly, from these systems principally that those muscles by which we whistle, whisper, speak, direct the organs of the nerves in the proper discharge of their functions, and effect the various movements of the head, trunk, and extremities, are found to be supplied. Accordingly, in effecting the former series of processes, the respiratory nerves are more frequently in requisition, and in effecting the latter the proper motiferous and regular. Thus, when we respire, as actuated by the ordinary stimulus of sympathy and passion or instinct, it is by means of a smaller or greater number of the proper respiratory nerves, in proportion as this process is less or more energetic, that we do so; but

and more recently by Fallopi (Obs. Anat.), Willis (Anat. Cereb.), Tissot, Cabanis, and numerous other writers; but the subject of the plurality of the nervous system had, nevertheless, been almost lost sight of in books, as well as in schools of anatomy and physiology, till it was revived and presented to the world in a collective form, and with many additions, by Dr. Gall, as it was subsequently by Sir Charles Bell; to whom, in conjunction with his contemporaries, we are indebted for our knowledge of almost all which has been established on the subject.

(*a*) It is only very lately that it has been tolerably well ascertained that the nerves above enumerated as motiferous arise, not any of them from the brain, but all from the spinal cord; and that there are not, in fact, any cerebral nerves in the body, all those belonging to the cerebro-spinal system, whether respiratory, motiferous, sensiferous, or regular, although they may pass through certain parts of the brain in their course, actually originating below this organ. Thus the source of the motor oculi is stated by Vieussens, Morgagni, Winslow, Lieutaud, Soemmering, and others, to be the crura cerebri, that of the motiferous portion of the lower maxillary branch of the trigeminus by Meckel, Haller, Wrisberg, and Vicq d'Azyr, the tuber annulare, and that of the abductor and hypoglossal by most authors again, the crura cerebri; so that it is only with respect to the regular nerves among those now under consideration that the doctrine above inculcated generally holds. It has been shewn, however, by Gall, who was one of the first to promulgate this doctrine, that the motor oculi is traceable to the anterior column of

the medulla oblongata—the summit of the spinal cord; by Santorini, Winslow, Soemmering, Bell, and Mayo, that the motiferous portion of the lower maxillary branch of the trigeminus arises from that portion of the same organ which is opposite to the corpora olivaria; and by Bell and others that the abductor and hypoglossal nerves originate in those portions of this organ which are opposite to the corpora olivaria and the spaces between them and the corpora pyramidalia. Whatever may be the case, then, with respect to the other cerebro-spinal nerves, it is certain that all those which minister to the voluntary motions are spinal and not cerebral; and, indeed, independently of autopsy and analogy, the simple fact that in a general palsy affecting the regular nerves of one side of the body, the proper motiferous nerves of the same side, and not of the other side are usually involved, renders it pretty clear that they all arise from the same organ; since, had the former arisen from the spinal cord—that is to say, below the point of discussion between this organ and the brain—and the latter from the brain—in other words, above this point—it is obvious that if the former had been palsied on the right side, the latter would in all probability have been palsied on the left, and vice versa. But to this subject further allusion will be made in future.

(*b*) It has elsewhere been explained that the ophthalmic ganglion, whence the bulk of the ciliary nerves arise, may be presumed rather to send filaments to the motor oculi and ophthalmic branch of trigeminus, than to receive filaments from them.

when, as in asthma, we respire by volition, or when we temper this process according to circumstances, we use the sub-occipital, cervical, dorsal, and lumbar nerves for this purpose. When we sigh, or yawn, or hiccough from either sympathy or passion, as is generally the case, the action is effected by means of the intercostal and phrenic nerves, acting simultaneously, in the second case, with the respiratory portion of the facial, and when we sneeze, groan, scream, sob, laugh, or cough from these ordinary stimuli, we do so by means of the abdominal nerves, together with the respiratory portions of the pneumogastric as distributed upon the larynx and other parts; but when, on the contrary, we effect these processes voluntarily, we employ on the one hand the sub-occipital, the cervical, and dorsal, and on the other the lumbar nerves, together with the motiferous portions of the facial and pneumogastric nerves for that purpose. Again, the processes of receiving aliment and transmitting it to the pharynx, of excreting the stools and urine, and of copulating, as excited by the usual stimuli of sympathy and passion or instinct, are effected by the agency of the respiratory portion of the facial, the glosso-pharyngeal, pneumogastric, abdominal and other respiratory nerves, but as exerted by volition, by the motiferous filament of the lower maxillary branch of the trigeminus, the motiferous portion of the facial, hypoglossal, sub-occipital, cervical, dorsal, lumbar, and sacral nerves. As the involuntary motions of the nostrils also, as well as of the eye-brows and features of the face generally, and their motions are usually involuntary—depend upon the respiratory portion of the facial nerve, so their voluntary motions depend upon the motiferous portion of the same; and as the usual involuntary motions of the eye-lids—as far at least as closing them is concerned—depend upon the respiratory portion of the facial nerve, and those of the eye-balls upon the pathetic nerve, so the voluntary motions of both depend upon the motiferous portion of the facial, the motor oculi, and the abductor. On the contrary, to the motions of the lips and tongue, as instrumental to whistling, whispering, and speaking, the ordinary stimulus is volition, and their processes are consequently effected respectively by the motiferous portion of the facial nerve and hypoglossal nerve. The same is the case with those of the nostrils, eye-balls, and external ears, which are subservient to the proper functions of these several organs, and they are effected accordingly by the motiferous portion of the facial, the motor and abductor oculi, and some of the cervical nerves; as well as with those lastly which minister to the various movements of the head, trunk, and limbs, which are excited therefore by the sub-occipital, cervical, dorsal, lumbar, and sacral nerves.

II.—The proper motiferous system of nerves, and that of the motiferous portions of the regular nerves, are in immediate union by their central parts with the proper sensiferous system, unlike the respiratory system, which is quite distinct from both; and it is hence easy to understand why, while the operations of the respiratory system are independent of those of either of the other two, these latter should in general act, as during watching, and cease from acting, as during sleep, almost simultaneously, as well as why each is in general more or less involved in cerebral apoplexy, and all general diseases affecting the other. This union, however, is not so intimate but that either may, under certain circumstances, continue in action or have its action suspended independently of the other; and, indeed, we are all conscious that, in the gradual processes of falling asleep and awakening, the function of sensation in the one case is longer maintained, and in the other is sooner restored than that of voluntary motion. The phenomena of palsy and incubus also abundantly prove that the failure of these two functions is by no means always in the same degree or even necessarily coincident.

III.—The proper motiferous nerves also, and the motiferous portions of the regular nerves also arise from a part which is directly continuous with the bulk of the brain, again unlike the respiratory nerves, which arise from a part not continued further than the tuber annulare; and it is thus easily explained why the action of the former systems, unlike that of the respiratory, should continue in general only during the action of the brain, and be suspended during sleep and coma, in which volition is intercepted, and why, as already observed, it should be commonly in a greater or less degree involved in the morbid conditions of that organ. Like the sensiferous system, however, the brain may be in action without the motiferous system, as in palsy of voluntary motion alone, in incubus, and in trance, or the last-mentioned system may be in action without the brain, as in somnambulism and walking catalepsy, as well as in palsy of sensation alone, combined with cerebral apoplexy; and numerous are the diseases which show that lesions of either the motiferous system of nerves or of the brain may excite the one quite independently of the other (a).

IV.—The inferior animals are found in general to possess motiferous nerves precisely corresponding to the voluntary motions which they severally perform; and these nerves, as well as their common source, are observed to be in general large in proportion to the force and energy of these motions. In the greater number of the invertebrate tribes,

(a) The following tabular view of the state of the anterior columns of the spinal cord,

the motions of which appear to be more frequently sympathetic or instinctive than properly voluntary, and the sensations of which are not perhaps very acute, the bulk of that portion of the nervous apparatus which corresponds to the distinct cerebro-spinal system of vertebrated animals is, perhaps, rather respiratory than either motiferous or sensiferous, and consists principally of nerves corresponding to the glosso-pharyngeal and pneumogastric—but it is impossible in them to draw any precise line of demarcation between these three departments. We know only that nerves for motion proceed in them to the tentacula, the legs, the tail, and other organs; but whether these nerves be respiratory or proper motiferous—in other words, whether the motions which they effect be sympathetic or instinctive, or properly voluntary, we are incapable of determining. In the vertebrated tribes, on the contrary, the voluntary motions are more easily distinguished from the involuntary, and in them accordingly we meet with motiferous nerves in the same degree distinctly developed. Thus, in such tribes as have the eye-balls moveable, as there is a pathetic nerve for its involuntary movements, as well as for those of the iris, so there are a moter oculi and abductor for such as are voluntary; and it is remarkable, that in those fishes in which the iris is a voluntary muscle, it derives its chief nerves directly from the former of these (*a*). As again they have a glosso-pharyngeal nerve for the instinctive process of taking aliment, so they have a motiferous portion of the lower maxillary branch of the trigeminus for the voluntary movements of their jaws; while, having no voice, and consequently never using their tongue in any attempt at articulation, they are quite destitute of a hypoglossal nerve. The same correspondence is observable, on the one hand, between the other involuntary motions of fishes and their pneumogastric nerve, and, on the other, between their other voluntary motions and the motiferous portions of their regular nerves; and if we follow these relations through the tribes of reptiles, birds, and mammals, we shall find this correspondence between the voluntary movements of each, and the development in them of the motiferous nerves, equally well maintained. How much greater, also, is the relative size of the spinal cord—*anterior and posterior columns collectively*—of brutes than of man has been already noticed—a circumstance which strictly corresponds with the greater force and energy of the voluntary motions as well as of the sensations, as contrasted with the intellectual operations, in the former than in the latter.

V. It would be reasoning in a circle to adduce the similarity in structure of the respiratory and motiferous nerves first, as a proof by analogy of the former being the channel of sympathy and passion or instinct, upon the presumption that the latter are that of volition, and afterwards as a proof by analogy of the latter being the channel of volition upon the presumption that the former are that of sympathy and passion or instinct. Taking it as abundantly established, however, by other circumstances, that the office of the motiferous nerves is what is here ascribed to them, it was quite allowable to bring forward this similarity as an argument for attributing an analogous office to the respiratory nerves; and it is not less so, assuming it as if not proved, at least rendered highly probable by other circumstances, that the respiratory nerves do perform the office which has been assigned to them, to adduce this similarity as a further corroboration of the fact already established with respect to the motiferous.

VI. The same remark may be extended to the further analogy between these two systems of nerves in their competency to convey the galvanic aura—as calculated to establish the office of either—that if other reasons exist for regarding the one as the channel of volition, while the other certainly is not so, this analogy may strengthen one opinion, that this other is the channel of some analogous power; and again, if we have good reason, from other circumstances, to believe that the latter conveys sympathy and passion or instinct, while the former certainly does not, we may fairly employ this analogy to strengthen our belief that it conveys some power of a similar description.

of the posterior columns, and of the brain, in the various affections in which they are severally or collectively involved is, perhaps, an approximation to the truth.

REMARKS

ON THE

TRIAL OF ROBERT REID,

FOR THE MURDER OF HIS WIFE,

BEFORE THE HIGH COURT OF JUSTICIARY,
AT EDINBURGH,*On the 29th of June, 1835.*

By JOHN FLETCHER, M. D. F.R.C.S.E.

LECTURER ON PHYSIOLOGY, AND ON
MEDICAL JURISPRUDENCE.*(Concluded from page 107.)*

5th. From what has preceded then it seems fair to doubt, if not expressly to deny, that there was, in this case, any real *ecchymosis*, any escape of coagulated blood from the discoloured parts, or any rupture of the jugular vein at all. The next point to be considered is the alleged fracture and dislocation of the vertebra dentata. For the sake of the non-medical public I must explain that the second vertebra of the spine, or vertebra dentata, sends upwards from the fore part of its body a tooth-like appendage, called the *processus dentatus*, which is received into the fore part of a ring, formed by the first vertebra or atlas, so that a blow inflicted upon the vertebra dentata from behind might, by driving forward its body, snap off this appendage against the fore part of the margin of the ring of the atlas, and thus allow the vertebra dentata to slide out of its natural situation. It is this which is presumed to have occurred in the present instance, and to have been the immediate cause of death, by the pressure thus made upon the spinal cord. But—to say nothing at present of the latter point—what evidence have we that the vertebra dentata was in fact fractured and dislocated? Were the bones in question forthcoming, as they should have been, at the trial; or, if not, what had become of them? It is hardly credible that it was coolly confessed that one of the *medical* gentlemen on whose testimony the case for the prosecution principally rested had, with a degree of carelessness perhaps unexampled in a judicial investigation of such moment, thrown them away, after their removal from the body by the other, “*with a parcel of beef-bones*!”—a slight specimen of the care and attention with which we may presume the other parts of the proceedings, even supposing him to have been otherwise competent to the office, were conducted. The best evidence of the fact of the fracture, as well as of the state of the bones, whether healthy or diseased (a circumstance, as we shall see directly, of vital importance) was thus withheld, and the prisoner was deprived of the advantage which might have resulted from their production. Had they been exhibited in court, and examined by careful and competent persons, disease might have been detected, and the fracture, if there really were any, traced to that cause.

But allowing that the bone was really fractured and dislocated, either at the time when it was described by Dr. Forbes on the trial as so found, that is to say, between nine and ten o'clock on the Monday morning—*forty-eight hours* after the supposed murder—or at the subsequent exhumation of the body on the Friday*; is this fact not as easily reconcilable with the presumption that the accident took place after death, as that it was the cause of the fatal event; nay, is it not even more easily reconcilable (supposing the evidence of the *ecchymosis* to be disallowed), with the former presumption than with the latter? When the corpse was first found, at half-past two o'clock on Saturday, the position of the head was, if not quite erect, as stated by the witness Ness, at any rate only a little inclined backwards and to one side, as deposed by Chisholm and Manners; “*just like a usual corpse*,” as remarked by Ness, who had been accustomed to stretch dead bodies, “*and not the least like us if the neck was broken*,” and it further appears, from the evidence of Young and Chisholm, that the head did not change its position when the body was shaken by the hand of the latter applied to the shoulder, with so much force as to change the position of the hand which was upon the floor, so as to turn the palm upwards. Is this consistent with the presumption of a fractured and dislocated neck; nay, does not Dr. Forbes himself admit that “the head would have dangled, when the shoulders were shaken, if fracture and dislocation had previously existed?” It is true the rigidity of death might have prevented this, and, had the alleged injury been received when the body was recumbent, so that the head was prevented from assuming the dangling position natural after such an occurrence, might have held the head in the posture described even under this discipline. But, not to recur to all that has been already said against the probability of such rigidity having taken place at this time, the body was, in fact, *not* rigid—the neck, the arms and legs, and the whole body were perfectly flexible, as already stated—the neck in particular so much so, as to allow of the head being immediately placed without any difficulty on a chair, as was done by Cherry Manners, who raised it by the chin and back part, and must have noticed any preternatural looseness of the neck; had such

* From the medical report made by Dr. Forbes and Mr. Williams to the sheriff on Monday, the 22d of September, it appears that the *dislocation* alone was discovered at this time, the *fracture* being mentioned for the first time in the report of Friday the 26th, the discovery of this having apparently taken place only on the body being disinterred and the bone removed: but this is only one of the numerous inconsistencies and anomalies with which this memorable case abounds.

existed. The fracture and dislocation of the neck then had not taken place at this time, and could not therefore have been the cause of death. Nor was this accident discovered at eight o'clock on the evening of Saturday, when the body was examined by Mrs. Fife, Mrs. Thomson, and several others; nor at eleven o'clock, when it was re-examined by Mrs. Fife, Mrs. Thomson and James Fife, in company with Bailie Walker and Williams. Williams indeed pretends to have detected it on the Sunday; but he certainly never stated his discovery either to Bailie Walker or to Dr. Forbes previously to the examination at which he was present with the latter on the Monday; and Dr. Forbes in his evidence sneered at the idea of Williams having before that time entertained the least suspicion of it. And in the mean time how had the body been tossed about on chairs, and beds, and stretching boards, and how had it been mangled! To say nothing of the probability of this accident having occurred during some one or other of these numerous examinations by unskilful persons, it appears that no adequate precautions were taken by the authorities to prevent access to the room in which the corpse lay in the intervals. No seal was placed on the door, as it should have been; and the key was left in an adjoining apartment, at the command of any body who, in idleness or malignity, might choose to tamper with the corpse. And with respect to the mangling, let us remember that on the Sunday the head had been more than half cut off, as appears at least from Dr. Forbes's account of one of Williams' incisions, "that it extended from one jugular vein to the other—as deep as it would go—*close to the bone*—as far round as the angle of the jaw!" No wonder that Dr. Forbes noticed on the Monday, when he saw the body for the first time, the "looseness of the neck;" and he was hence led to suspect a fracture of the processus dentatus, and a dislocation of the second vertebra upon the atlas, although he appears to have taken no means of verifying his suspicion, except that of thrusting his fingers into the chasm aforesaid, when he detected, on making the head revolve, such "a rasping and grating" as confirmed him in his conjecture. Is this all that an accomplished surgeon would have done on such an occasion, and would such a one have allowed the body to be buried, and subjected to the further violence of exhumation four or five days afterwards, before the alleged fact was properly established? It is extremely doubtful, as remarked by Professor Lizars, whether such an injury as this could possibly be ascertained by the means first employed, some diseases of the bones being competent to produce a very similar sensation to that above described*; so that we have the additional

probability of the alleged fracture and dislocation having in fact taken place during the disinterment—perhaps one of the most common causes of this accident. The presumption is, as will appear more fully in the sequel, that the woman had laboured under a disease of the upper cervical vertebræ—a presumption which is in strict accordance with the only one hitherto admitted, namely, that she was predisposed to spasmodic affections—and that the repeated acts of unskilful and perhaps wanton violence, to which the body was subjected after death, had produced the injury in question. I do not require to be told that such a fracture and dislocation of the vertebra dentata is not a common accident after death, or that it is often in vain that we attempt to fracture the processus dentatus in subjects brought into dissecting rooms. Such a fracture, however, does sometimes occur even when the bones are sound; and the experiments made to effect it would perhaps have been more frequently successful had the head, as in this instance, been half cut off as a part of the process. At any rate when the bones are diseased, as was probably the case in this woman, it not unfrequently occurs even spontaneously, and may easily be supposed likely to result from much less handling and mangling than was in this case employed. Let those likewise who ridicule the idea of this occurrence, and represent it as next to impossible to effect a fracture of the processus dentatus in the dead body, take care that they do not, like green logicians, prove too much for their purpose. For if, in the dead body, it is *next to impossible* to effect it, provided the bones are sound, in the living body, when the resistance of any injury is so much greater, and particularly in a person lying in bed—as is presumed to have been the case in this instance—when the resistance of any force calculated to effect a change in the relations of the bones of the spine would be of course immensely increased, it may be presumed to be *entirely so*: consequently Reid could not have murdered his wife by this means if the bones had been sound, and if they were otherwise, the occurrence of this accident is no evidence of violence at all. But to return to the facts of the case. It is asserted that the processus dentatus *was* in this instance fractured, and that the bone, when at length removed from the body, was found to be perfectly healthy; but upon what evidence does the latter fact rest? Dr. Forbes says that "the bones were sound, as far as he could see," and Professor Christison, that "no material disease could exist if the bones appeared sound;" but with how much greater justice was it asserted by Dr. Robertson that it would require minute examination, and perhaps even maceration, to ascertain the presence of certain diseases which would render the bones preternaturally frangible. But the bones in this case were not particu-

* See Note, p. 53, line 1.

larly examined, as confessed by Dr. Forbes, at the time they were removed; and, before he had a second opportunity of seeing them, had been tossed away by his colleague with a parcel of beef-bones! And with what degree of care was the state of the contiguous parts and of the rest of the body investigated? No notes whatever were taken during the examination. The periosteum or membrane covering the bone, on the surface of which Professor Christison admits that "blood should have been found had the fracture occurred from violence inflicted during life"—the vertebral canal, which would in all probability have manifested further marks of the injury—and the spinal cord, from the effects upon which alone such an injury could have proved fatal—(will it be believed?) were not examined at all. The examiner "could not say whether the jugular vein was cut through or not." None of the internal organs, with the exception of the brain, which appeared healthy, were ever thought of. Almost the only part looked at, except the aforesaid reputedly sound bones, was the transverse ligament which confines the processus dentatus, and which was *not* ruptured. "No extravasated blood," says the examiner, "was seen more than in an ordinary dissection." And yet this gentleman still maintained "that the fracture of the processus dentatus was the cause of death;" and others, who had expressed an opinion to the same effect perhaps before they were aware of the extreme slovenliness of the proceedings on which it was founded, did not hint at a doubt or qualification of this opinion, when that slovenliness must have been so manifest, but continued to cling to the dogma that there was "no rational way of accounting for these injuries except by a blow," and that "Mrs. Reid had died by violence!"

6th. The finding of the axe in the prisoner's room, somewhere about the grate—the very last place, by the way, where he would in all probability have put it, had he made it the instrument of murder, as it would of course be the first place where such an instrument would be sought for—is of no importance, otherwise than taken in conjunction with such manifestations of violence as might be supposed to have been inflicted with such an instrument, the evidence of which is so inconclusive. I may just observe however that it must have been an axe of unequalled powers if it could, at one blow, produce an extensive *ecchymosis* under the right ear, across the shoulders and down the back as far as the loins, a rupture of the right external jugular vein, "the resemblance of a blow or a concussion" behind the left ear, and a fracture and luxation of the vertebra dentata; and the presumption of more than one blow, or even of one blow, having been struck with such an instrument is inconsistent with the non-appearance, particularly in a weak, ema-

ciated subject like Mrs. Reid, of the least abrasion or puckering of the skin, as distinctly deposed by Mrs. Chisholm, Mrs. Ness, Mrs. Fife, and Dr. Forbes himself. The blunt extremity of the axe produced in court was bounded by four pretty sharp angles, and there was in one corner of it when found, as noticed by Dr. Forbes, a *portion of dust remaining*. It could not therefore have come down flat; and how an instrument of this kind could have inflicted a succession of immensely forcible blows, or even one such blow, coming down obliquely on the body, without leaving any external traces of its action, I am at a loss to conceive. Moreover the blow or blows are presumed to have been inflicted while Mrs. Reid was in bed, lying probably on the right side, a posture which, from the plan of the apartment exhibited in court, would have brought her face to the wall, so that the man must have stood behind her while inflicting it; and how he could possibly, in this situation, so apply an axe to her body as to produce, I do not say all the injuries, but any one of the injuries in question, is to me equally incomprehensible.

So much then for the validity of the evidences of any violence whatever having been offered to this woman, constituting in this case the *Corpus Delicti*. We have seen that, of these reputed evidences, the majority are founded on presumptive facts, which not only hinge on statements so questionable as to be altogether unworthy of credit, but are inconsistent, as well with one another, as with common sense; while the remainder, even if the facts on which they are founded be admitted, furnish no evidence at all. The proof of the violence being so defective might perhaps supersede the necessity of entering at all into the *moral circumstances* of the case, from which it was inferred that Reid was the inflictor of that violence; since where there is no crime, there can of course be no criminal. It seems proper however, as great importance is attached by some people to these circumstances—and they certainly would, if really valid, add weight to the presumption, in a doubtful case, of violence having been committed—to show that, in this instance, they are not such as to add either proof or probability to this presumption.

7th. It appears from the evidence of Isobel Young that the prisoner was in the habit of cursing and swearing at his wife, "of calling her a dirty brute, and telling her to stand out of his road," and of using threatening expressions towards her; from that of John Arnot, the brother of the deceased, that on one occasion, he told her to go home "or he would break her neck;" and from that of Mrs. Fife, that, at another time, he desired her to hold her tongue, "or he would rise and choke her." But how continually coarse and sanguinary expressions like these are employed by persons in the lower ranks of life, and with ill-regulated minds, on every trivial

provocation, without any deliberate purpose of mischief, must be known to every body; and when we reflect how frequent and grievous were the occasions of irritation which this wretched woman gave her husband by the filthy practices resulting from an infirmity to be in future alluded to, we may easily conceive that he would now and then express himself in no measured terms towards her. But his demeanour might be nevertheless on the whole any thing but ferocious; and indeed it is admitted by Isobel Young, as well as deposed by Mrs. Crichton and others, that when his wife was ill, as already stated, a few weeks before her death, he behaved to her with the greatest kindness and attention. Mrs. Crichton further states that Reid and his wife always appeared to her to live together "on very good terms;" and Henry Russell says, that he saw them "standing cracking together in a friendly manner, and him patting her on the shoulder," on the very evening of the day before the supposed murder was committed. If *an ill tongue* and the horrible menaces sometimes employed by persons like Reid were in all cases to be taken as indicative of the *animus* by which they were actuated, there are few inhabitants of our closes and wynds who would stand clear of an imputation of murder, on any occasion of death which took place among their associates.

8th. But, according to the witness Chisholm, Mrs. Reid was accustomed to complain that Reid did actually sometimes strike her on the head; the witness Arnot deposed that he had heard her say, "He's aye knocking me on the head, and he'll kill me some day;" and the witnesses Isobel Young and Mrs. Fife stated that she was in the habit of crying out as if struck, and that about twelve o'clock on the night before the supposed murder, she was heard, soon after he had told her to "lie yont," or nearer to the wall, to exclaim, "Don't hit me on the head—take my life at once." It is extremely singular however that no one of the above-mentioned witnesses, nor any other of the numerous persons who appear to have lived almost in common with Reid and his wife, deposed to ever having *seen* him strike her—they only *heard* her occasional complaints and exclamations; and if it be admitted that she had a disease of the upper cervical vertebrae—as already supposed, and as will in future be rendered more than probable—since it is a characteristic mark of such a disease for the sufferer to feel acute pain, and to apprehend fatal injury from the slightest collision of any thing with the head, all these may easily be accounted for without the presumption of her having suffered any actual violence. The last and most appalling of these expressions was used when the parties were in bed together with their child, and when it is not only extremely improbable that any violence whatever was employed, but certain that it was not of a murderous description, since she was

certainly alive, and was heard to speak, as appears from the confident statement of Isobel Young, at nine o'clock on the following morning. And if in this instance she cried out murder, when probably all that she sustained was a slight push in order to make her lie further off, or perhaps to awaken her, and prevent the common effects of the infirmity just spoken of*, all her complaints and exclamations at other times sink into nothing: she was probably worse at this time than common, from the fatigue which, as we shall presently find, she had undergone the preceding day, and therefore more sensible of the least impulse, and more apprehensive of danger than usual. It appears further improbable, from Reid's general character, that he was really cruel to his wife. The witness John Piggot, who had known Reid for several years, and lived in the same "land" with him, "never saw any thing but harmlessness about him;" and Mrs. Lenny who had been for some time his neighbour, never regarded him as otherwise than "a simple man." And indeed Mrs. Reid's complaints of him do not appear to have been very consistent, since Mrs. Finlay or Smith, to whom she seems to have unfolded all her troubles, distinctly states that "she never complained of her husband."

9th. And with respect to the agitation of the prisoner when taxed with the murder, soon after the discovery of the corpse, what does this amount to? To Young and Manners, in answer to their interrogatories as to whether he had not done any thing to his wife, he replied, "No, as sure as God is in heaven;" but when taxed with the murder by John Arnot, the witness and Mrs. Tod "thought he turned a little white." And what if he did? There is many an innocent man who would have done the same under a similar imputation. It was after this that he used the ambiguous expressions, in answer to a question by Mr. Grieve of what complaint his wife had died, "We must not tell all things," and "all things go as they come;" and, supposing these words to be ambiguous†, what was more natural than for a drunken man, as he then was, under such circumstances, to affect great circumspection in his discourse, and to have recourse to the wise words and dark sayings in question? The answers savour much more of the mock solemnity of a fool, than of the crafty purpose of a villain, and are very different from what we should expect from one who had committed murder, and who would have felt that such expressions were calculated to excite, not to

* This is the statement made by the prisoner, in his declaration before the sheriff, on the 27th of September.

† It has been imagined that Reid, in these replies, alluded to the infirmity of his wife, above spoken of; and in this sense the words are simply absurd—they cease to be ambiguous.

allay suspicion. And a similar remark may be made with respect to his subsequent declaration of satisfaction at being released from his wife. When first aware of her death he was very much affected and "concerned-like," as stated by Mrs. Crichton, Mrs. Lenny, William Duncan and others; and, according to Mrs. Tod, shed tears so copiously that they streamed down his cheeks. Now these tears were either real or affected. If they were real, it is most improbable that Reid had committed the murder imputed to him; if they were affected, it is most improbable that he would, had he been a murderer, so soon afterwards have made the above declaration, which was so inconsistent with them. The fact appears to be that the tears which the man at first shed were the instinctive expression of emotion at the loss of a woman to whom he had been united for twenty-four years, and that the declaration afterwards made sprung from a rational conviction that this paralytic, miserable woman had really been, as he said, "a burden to him and to every person else." That these tears could have been immediately commanded by a guilty man, or even that they would have been sought for by one at the time very much intoxicated, is almost incredible; but admitting that he possessed sufficient self-possession and art to produce these tears, he would surely have possessed too much so soon afterwards to pull off the mask, and to make a remark, not only so inconsistent with the farce which he had been previously playing, but so well adapted to strengthen any prejudice which might exist against him. His subsequent expression to Mrs. Tod of regret at not having treated his wife worse than he had done is precisely what might have been expected from a low, drunken fellow, when goaded by the manifestations of suspicions which he felt that he had not deserved, but the last thing in the world to be expected from one who had actually committed the murder of which he was suspected.

10th. And the absence of any distinct purpose of deception is equally obvious from his denial at one time of having been at home at two o'clock, which, so far from tending to criminate him, serves, in my mind, rather to exonerate him from any suspicions which the rest of his demeanour might have excited. It appeared in evidence that it was in immediate consequence of this visit to his house at two o'clock, that he applied to Mrs. Tod to come over to the assistance of his wife; so that his assertion of not having been at home at this time, which—as connected with the peculiar posture in which the corpse of his wife was found, and in which he pretty certainly then placed it—has been considered of so much importance, carried with it its own refutation. He was drunk and agitated, and neither knew at the time what he was doing, nor afterwards what he had done; and while this falsehood is thus easily attributable to the

general perturbation into which his own intemperance and this unfortunate business together had thrown him, it indicates an absence of *dole* in this matter quite incompatible with the deep design which he is presumed to have displayed in other respects.

11th. Again, how perfectly natural was the solitude of Reid, occupying, as he did, with his child a single, miserable room, to have the loathsome remains of his wife as soon as possible removed, or at least concealed in a coffin. Was it to be expected that he should submit a moment longer than was necessary to be surrounded by the horrors of death, in addition to the filth and vermin by which he had been so long annoyed and exasperated? It is all very well for persons enjoying every comfort and luxury, and who can *afford*, not only to cherish every finer feeling, but to subscribe to all the pomp and circumstance of civilized life, to talk of the coarseness and indecency of Reid's conduct in seeking so soon to immure his deceased wife, and to infer from that a presumption that he had murdered her; but this circumstance can have no weight whatever on the minds of persons in the least degree versed in the history of the squalid wretches of the class to which he belonged. He thought only of his abject misery, and the means of alleviating it.

12th. Lastly, with respect to his alleged confession of the murder to the officer who apprehended him on Monday, on his return to Dysart after his visit to Edinburgh. When first apprehended he manifested great surprise, and asked, "What is't—what is't?" And it was proved in evidence that he had been urged to this confession by the hope so unwarrantably held out to him by the officer, who desired him to say "he had got a dram, and confess he did it, and he would get off," while he was "sure to be hanged," he was told, if he denied it. This is distinctly stated by Mrs. Gray or Smith, the jailor of Kirkealdy, and by Michael Slater, sheriff-officer. Reid was a weak, muddled creature, in the hands of officers of justice—alone and unadvised—and he believed them. Accordingly when he was examined before the Justice of the Peace on the same day, he positively denied murdering his wife, and mentioned the reason why he had made a different statement to the officer. The mere circumstance indeed of his having returned from Edinburgh to the seat of the supposed murder, when he might so easily have absconded, is a presumptive proof of his innocence. Had he been a murderer he either never would have returned, or, had he returned, he would have been better prepared to meet the snare thus laid for him, and to have escaped it.

Such, then, are the principal alleged moral evidences of Reid's guilt. Singly or collectively they prove nothing more than that he was a poor, stupid creature, who had become an idler and a drunkard from the wretched-

ness of his home, and who lived on no worse terms with his wife than thousands of others in the same rank of life, who have not the same excuse for their dissipation. I have said nothing of the opportunities which he had for the commission of the crime with which he was charged, since the circumstance of his having had these opportunities does not in the least strengthen the presumption against him—it only deprives him of the strongest possible argument on the opposite side. That abundant opportunity was afforded him for committing the murder in the manner supposed at a little after nine o'clock, and of placing the corpse in the attitude described at two, is unquestionable; but his having had these opportunities of doing what is imputed to him furnishes no manner of proof that he availed himself of them. And when we reflect that the neighbours, and in particular John Fife and his wife, who could distinguish every sound in Reid's room, and were taking their breakfast at nine o'clock, heard no sort of noise or scuffle—that Reid's little girl, a child of seven years old, was in the apartment during the whole time of this visit, and was met immediately afterwards by Isobel Young on the stairs with her father, not betraying the least agitation—and that Reid, after remaining half an hour in the house, left it quietly and composedly with his child*, and, upon rejoining Duncan at ten o'clock, displayed nothing whatever unusual in his manner, the presumption is that such opportunities were not so employed, and that the death of his wife took place at some time between these two periods, from natural causes. Nor is it at all incumbent on those who adopt this opinion to show what these causes were. It is quite sufficient to have entitled the prisoner to an acquittal, to neutralize, as was done, the testimony against him: but when, in addition to this, we find that it was rendered in the course of the trial highly probable, not only that this woman had died a natural death, but that such an event might have been rationally expected almost precisely at the time it occurred, there is surely no one who will grudge him the very equivocal verdict which was passed upon him, while some will perhaps think that the verdict of "not guilty" might have been mercifully substituted for that of "not proven."

* Some stress has been laid upon the circumstance of Reid having, on this occasion, taken the key of the house with him. But it appears that it was not very unusual with him to do so; and it is certainly difficult to conceive why he should have preferred, had he committed the murder, allowing the circumstance of his wife's death to transpire in a manner so well calculated to raise suspicions against himself, to incurring the risk of her being found dead in her bed during his absence, which would have been looked upon probably as a mere every-day occurrence.

It was proved in evidence that the deceased was fifty-six years of age, and accustomed to miserably poor fare—that she confessed to having had an attack of palsy (Tod)—that her head shook—(Ness, Mrs. Fife)—that her voice was feeble and querulous (Mrs. Fife)—that in walking she inclined very much to one side (Young, Crichton, Mrs. Fife and others)—and that she was in the habit of passing all her natural discharges in bed, alleging that she could not help it (Young). She was constantly putting her hand to her head (Arnot), and complaining of pain both in the head (Young, Chisholm, Crichton, &c.), and in the back (Crichton), and was in every respect "a silly weakly woman" (Ness)—"silly both in body and mind" (James Fife). Now what would any medical man say was this woman's complaint? If he were called upon to describe the symptoms of a diseased state of the vertebral column involving the functions of the spinal cord and brain, he could hardly do better—as may be inferred from the evidence of Drs. Robertson and Mackintosh and Professor Lizars—than enumerate those manifested by this unfortunate woman; and her apprehension of the most imminent danger from the slightest impulse affecting her head is further characteristic of the same disease, and leads to the belief that its principal seat was about the vertebra dentata and atlas. But, while we admit these facts, it may be objected to them as furnishing any evidence of Reid's innocence, that the primary cause of the disease which they indicate, as well as the immediate cause of death, might be the violence which she suffered from her husband; but—not to recur to the very inadequate evidence on which the presumption of any such violence rests—it is more than questionable whether any habitual violence could have induced a chronic disease of this description, however competent an individual act of violence might be to occasion death. Further, Mrs. Reid some weeks before her death suffered a spontaneous attack, from which she became speechless (Young, Crichton); the body was quite cold and the limbs stiff—so much so, that it was with great difficulty that they changed her linen—and it was believed that she was dead. Who can doubt that this was an attack of spinal apoplexy, which is quite consistent, as indeed is cerebral apoplexy also, with a perfectly healthy appearance of the brain? Had the woman died at this time, if the fit had seized her in any other than the horizontal posture, who can say in what extraordinary attitude the limbs might have been found; who can question that had the corpse been placed afterwards on the back, livid marks would, after a time, have displayed themselves on the skin of the neck and spine; and where is the improbability that, presuming the attack to have originated in a diseased state of the vertebral column, a very slight wrench or other violence would have afterwards occasioned a fracture or luxation of this part? It was precisely this in all pro-

bability which was destined afterwards to occur. From the attack which she at this time experienced she never entirely recovered. She became more frail, and more querulous (Crichton, Lenny); and what medical man would not now have said that her life hung by a thread, or would have been surprised if she had, at no distant period, a second attack, which would suddenly finish her miserable existence? On the day preceding that on which she died she had hobbled, according to one account (Finlay or Smith), to Colddeans, above Kirkcaldy, more than two miles from her own residence; according to another (Chisholm), as far as Clunie's Square, four or five miles off. She was seen at Kirkcaldy, on her return, by Mrs. Gray or Smith, the jailor, inclining more than usually to one side, "all shaking," and apparently so exhausted that the witness "did not think she could go much further." On arriving at Pathhead, she was seen by Lenny, Finlay or Smith, Henry Russell, and others, who severally deposed that she was on that evening walking so much to one side that one arm almost touched the ground, and the clothes on that side were hanging off the shoulder—that she looked sickly and "gorged"—that she put her hand to her head, as if to support it—that she complained of being very much fatigued, and of the pain in the back being very sore—and that she expressed an apprehension that she had had another attack of "that trouble," and that she was going to die! What assemblage of exciting causes and symptoms could have indicated, in such a subject, a rapidly approaching dissolution, if this did not; and would it not have been to any medical man a matter of greater surprise if she had not been carried off within the next twenty-four hours, than it could be that she was so? It was in the course of this night that she was heard to utter complaints of violence offered to her head, and to beg to be killed outright—exclamations which, taken in conjunction with the immediately preceding symptoms, indicated only an aggravation of her malady; and where is the wonder that, in attempting to rise on the following day, a paroxysm like that which she had recently experienced terminated at once her sufferings and her life? If this woman were murdered, it was, by the most wonderful of all coincidences, almost at the very instant that her demise from natural causes might have been predicted*.

I presume not to determine whether this were or were not the case. Perhaps there

larynx towards the nape, and often to the scapula of the pained side. No external alteration is perceptible, but *firm pressure on the region of the first and second vertebra produces considerable pain*, and thus points out the seat of the disease. The difficulty of swallowing and breathing, and hoarseness increase, alternating with pain in the neck, which seems to fix about the back of the head, and becomes intolerable on moving that part. The head sinks towards one shoulder, the face being turned a little down; for in general the articulations are affected on one side only, and that was the left in seven out of nine examinations after death. If both sides are affected, the head will incline directly forwards. In this state things continue for several weeks or months; and before worse symptoms come on, there is often apparent improvement, freer motion and more natural situation of the head. But the *uneasiness in speaking* and swallowing returns, the pain becomes more severe and extensive, the head falls a little backwards, and sinks towards the opposite side. The patient feels as if the head were too heavy, and he carefully supports it with his hands when he moves from the sitting to the lying posture, or vice versa. This may be considered a pathognomonic symptom of the affection. Another symptom which at this period shows the true nature of the disease, is a peculiar expression of pain on the countenance, which, combined with the position and stiffness of the head, constitutes so characteristic an assemblage of appearances, that it is enough to have seen it once, in order to recognize it again immediately. In the further progress of the case, noise in the head, deafness, giddiness, cramps, and convulsions, partial paralysis, particularly of the upper limbs, loss of voice, purulent expectorations and hectic symptoms supervene. Generally no external change is observable either in the neck or in the nape, and Rust observed in one case only swelling of the affected side, which broke and left fistulous ulcers. But the slightest pressure in the region of the upper vertebrae is acutely painful; and sometimes, in the advanced period of the disease, a grating of rough surfaces is distinctly perceptible when the head is turned. The patient may continue for months in this helpless and painful state, and then dies either from exhaustion and debility, or, which is more frequent, suddenly and unexpectedly." (Medico-Chirurgical Transactions, vol. xiii, p. 406). In commenting upon this account of the disease in question, Mr. Samuel Cooper adds, "In cases of this description the joint between the atlas and occiput is never the only one which is displaced or deformed, unless the disease be very slightly advanced; for the articulation of the processus dentatus

* The following is the description given by Mr. Lawrence, after Rust, of the symptoms attending a displacement of the atlas by disease. "Pain in the neck, becoming more severe at night, or in swallowing a large mouthful, or drawing a deep breath, is the first symptom. This pain affects one side of the neck, especially when the head is moved towards the shoulder: it extends from the

were, as remarked by his Majesty's Solicitor-General, ample grounds for justifying the indictment laid against Reid; but I repeat what I began with, that there never was a case in which the evidence for the prosecution was more meagre, incongruous and disgraceful, while there certainly have been few which developed a concatenation of circumstances in favour of the presumption of the innocence of the accused more full, more consistent, or more satisfactory. The foundation stone of the whole edifice against the prisoner, was the bare word of one who was at once morally unqualified, and legally unauthorised to speak to any medical question whatever—of one grossly ignorant and unblushingly false, and whose only manifestation of common sense was his anxiety, as indicated by a succession of the most pitiful subterfuges, to avoid an exposure to which his shameless usurpation of an honourable and responsible post had subjected him. Not only were the depositions of this man entirely unsupported, but almost every word uttered by his coadjutor goes to disprove what he had asserted. And of what was the next part of the fabric—which, however, without the foundation stone in question could have availed nothing—of what was this composed? Namely of the statements of another, who, however, legally authorised he might be to substantiate a medical fact, or to deliver a medical opinion, conducted the *post mortem* examination, as deposed by all the medical witnesses for the prisoner, in such a manner as not to warrant the slightest reliance being placed upon it in the formation of any opinion as to the cause of death, and to draw from one of them the declaration that he “was quite ashamed of it.” Such was the basis on which the conclusions of the other medical witnesses for the crown were founded, and with this basis their conclusions must either stand or fall. Be it remembered also, that the opinions of the medical witnesses for the crown were founded on proof adduced on *one* side only, while the opinions of the prisoner's medical witnesses embraced the evidence on *both* sides; and a very great number of important facts, such as the total want of discoloration at eight o'clock on the Saturday, the sore on the head, the attack which the deceased had previously experienced, her frail state on the day before her death, and many others—all which should have been taken into account in forming a full and fair opinion on the subject—transpired only or chiefly in the course of the exculpatory evidence. In conclusion, I must observe that, whatever trivial inaccuracies may have been fallen into by the medical witnesses for the prisoner,

with the atlas, and sometimes that of the point of the same process with the occiput, are considerably affected.” (Dictionary of Surgery, ed. 1830, p. 392.)

they sink into less than nothing when compared with the fundamental failures of the opposite party. To omit the barefaced falsehoods above stated, such a display of helpless ignorance, of reckless negligence and of glaring inconsistency as this trial affords is perhaps unprecedented in the annals of modern medical jurisprudence; and, whoever may be the parties who choose to mix themselves up with persons capable of making such a display, they must not expect to be held blameless. In this case I have very unwillingly found myself opposed in sentiment to men for whose talents and acquirements I have a very sincere respect: but no consideration shall ever deter me from forming and acting upon my own opinion; and I hope and believe that the public, now in possession of the real circumstances of the case, will allow that, in this instance at least, the conclusions of these gentlemen were no less justly questioned, than they were successfully resisted.

M. BROUSSAIS'

Course of General Pathology and Therapeutics;
translated and revised

By JAMES MANBY GULLY, M.D.

LECTURE XII.

Buccal and Pharyngeal Inflammations, continued.

PURSuing our analysis of M. Bretonneau's work we find, that, to actual cases of croup, they give the name of false croups, asserting that such are catarrhs, whereas the fact is, that, being arrested in good time, they have not been fully developed. This method of only beholding diseases when they have reached their greatest intensity is sufficiently convenient for those who use it, inasmuch as it gives them the opportunity of saying to others who strive to arrest disease that they are wrong in supposing they have so arrested it, that it was slight, and would have stopped of itself—a sort of argument not unlike the answer of some patients whose gratitude is at a discount, and who think to acquit themselves by saying that their disease was a trifle, which would have come round of itself. Is not such a proceeding inimical to the progress of science and opposed to the generalizations without which it cannot exist? Is it not putting into practice the baneful art of dissimulation, and is it not impossible to go on reasoning with those who have recourse to such objections? Certain it is that we arrest all manners of disease in our hospital, as do our pupils daily; in proof of which we can produce lists of mortality which are considerably smaller than when we followed the beaten and vulgar paths of treatment. It is, therefore, a monstrous

error to imagine that it is necessary to wait until a disease has reached a certain point before we venture to say that it exists at all. Still they have profited by our advice, since they make every endeavour to prevent follicular phlegmasia of the tonsils from being propagated to the larynx and trachea, and have felt that once there, it can no longer be mastered. Yet, notwithstanding this, they rarely succeed; and why? because they address themselves to it at too late a period; they certainly attack the disease of the gullet by times, but it has already been for some time in another situation. The cases in which they have succeeded are those where it commenced in the most visible point, and that to which topical means were more readily applicable; the other cases, and these the most numerous, have been fatal, and hence the great mortality. But for these different results they are unable to account; nor have they introduced into the discussion of facts all the strictness such discussion demands. The mercurial treatment does not prevent the propagation of the inflammation, as we shall see in speaking of the therapeia of the disease. Here, then, I close my remarks upon the loose manner in which this subject has been treated; should you desire to go deeper into it, you may read, on one hand, M. Bretonneau's work, a work filled with valuable matter, and undertaken with excellent views, but ill executed, without order or logic, and one which, to be a classical work, should be remodelled by some methodical and closely reasoning mind; and, on the other hand, the complete and impartial refutation of it by M. Emangard in his *Traité pratique du Croup*, his *Memoire additionnel au Traité pratique du Croup*, and his *Memoire sur l'Angine epidémique ou Diphtherie*.

Proceed we now to reduce the confusion in which these diseases have been involved; for notwithstanding the pains I have taken to lay open to you the artificial arrangement that has been made of them, I am afraid that your ideas of them may still be obscure. I shall, therefore, strive to exhibit them in a more natural order.

The bucco-pharyngo-laryngean inflammations, like all other inflammations, are primary or consecutive; they do not consist in affections necessarily commencing in one point and finishing in another, this being only observed in specific inflammations, such as small-pox and cow-pox. The primary ones are first developed in the parts mentioned, the mouth, pharynx, and larynx; the consecutive ensue on visceral phlegmasiæ, and make their appearance at the openings of the great mucous membranes, when the deep-seated parts of the same membranes are inflamed. We have already observed, that the external phlegmasiæ are sometimes primary, at others secondary, and the same applies to every part of the body. Hitherto we have only stayed by the primary inflam-

mations, in order that you might more readily remark the mode in which they produce disturbance of the system; we will continue the same process with regard to the inflammations now under consideration, and will class them in the following manner.

1. Inflammations of the tonsils and velum palati, primary amygdalitis and staphylitis, without supersecretion, sometimes phlegmonous and sometimes not. This is the highest degree of inflammation.

2. Inflammations of the same organs with mucous exudation, likewise primary. Examples of this you may find in all epidemics, because the causes that produce these epidemics may have their effects confined to the organs we are now speaking of. You will see in this category various degrees of consistence of the mucus, from the most coherent to the other extreme. You will see these affections subdivided until they have only the name of aphthæ, a disease in which there is no thick and extensive concretion, but small white parcels or granulations scattered over the inflamed mucous surface, with supersecretion of saliva. This affection is not necessarily more consecutive than the others, and is seen without gastritis.

3. Phlegmasiæ of the gums, non-scorbutic, primary, and produced by cold, with or without concretion, common in our military hospitals. It is this disease that made such ravages in the army of Germanicus; now-a-days, when people know how to arrest disease, it is easily seen why it was so murderous, and how it might have been prevented from being so. For a like reason, all those great pestilences, which formerly decimated the human race, might be now considerably weakened, and even be made to disappear altogether.

4. Phlegmasiæ of the pharynx, primary, phlegmonous, or non-phlegmonous, with or without mucous secretion, membranous, or non-membranous, being all different degrees of inflammation.

5. Phlegmasiæ of the larynx, with the same distinctions as the preceding.

Such are the divisions to which we will conform; they include every possible case. For the rest, you may readily imagine that when a phlegmasia of a mucous membrane is violent, it suppresses the secretion of it, and that, consequently, there may be croups or inflammatory swelling without any kind of secretion, just as there are with mucosities and false membranes. When a patient is suffocating, the first thing is to find the seat of mischief and speedily apply to it; this you will be able to do readily, if you keep the above distinctions in mind.

For the present, we shall only treat of these diseases as primary; when you shall have been convinced that they may all be really so, you will be able to read the epidemics with advantage; but I should be putting you in an embarrassing situation,

were I to induce you to peruse their descriptions previous to teaching you how to unravel the confusion of them—it would be nothing but useless erudition and pure chicanism on my part.

The principal cause of these epidemics is cold, which suppresses the transpiration and makes a membranous affection to succeed it. If so many mucous membranes are affected at one time, it is owing to the impress of this agent on a vast surface whose action it stops, and it is a law of the system that on the cessation of action in one organ another supplies its place. Vital action, diminishing or ceasing in the skin, is conveyed to the interior; and if the secretory organs intended for normal eliminations are not prepared to receive it, or, in other terms, if they are unable to sustain an overplus of activity, a morbid condition obtains either in the lungs, in the stomach, or in the organs whose inflammations are now under our consideration; hence the prevalence of these epidemics in humid weather.

We will commence with the inflammations of the mouth, that is, of the gums and interior of the cheeks. These are produced by local stimulation. Dentition is one of the most evident causes in the evolution of both sets of teeth. Various other circumstances, such as dental phlegmasiæ and caries, may also assist in producing them. To these add sialagogues, pellitory, tobacco, chewed or in smoke, acid articles of food, brandy and other strong alcoholic fluids, ill conditioned water, food of difficult mastication, in short, any strong mechanical friction or stimulation. Cold also acts as a cause, by arresting the transpiration, and it acts still more violently in that character if the irritation of the gums previously exists as a predisposing cause. There may sometimes be a state of general congestion of the head and mucous membranes that keeps up these inflammations, and which very few authors have mentioned; when such exists, and suppression of any hemorrhage, of the menses or of epistaxis, an increased inflammation of the gums supervenes. In some cases, we have some ground for suspecting the contagion of gingival inflammation, when, for instance, it occurs in individuals who have made use of the same vessels as those already affected, or when any other kind of contact between them has taken place. This scarcely ever happens unless the inflammation is accompanied with membranous exudation and ulcerations, and even then a direct influence and a certain predisposition are requisite.

The inflammation may break out from the same causes in other parts of the mouth, in the internal surface of the cheeks, and on the tongue; the latter constitutes glossitis, which may be induced by local stimulation, and sometimes exhibit the aphthous and sometimes the phlegmonous character. It may even be followed by suppuration in the

substance of the tongue; this however is rare, in consequence of the small quantity of cellular tissue entering into the organ.

When inflammation of the mouth involves at once the gums, the tongue, and cheeks, and is accompanied with minute white exudations, the name of aphthæ is assigned to it. These exudations are sometimes moveable, and resemble portions of clotted milk spread over the inflamed mucous membrane; at other times they appear as if depressed in the membrane, which surrounds them like a hedge from its own tumefaction and their adherence, and they might be taken for ulcers. Such ulcers often really exist after the fall of the pellicle, and the consequent nudity of the surface. At first sight it is somewhat difficult to determine whether the aphthæ are owing to an exudation and concretion of false membranes, or consist of a superficial ulcer. Besides the causes I have assigned to them, and among which we must not omit cold, they generally require a peculiar predisposition; some individuals are naturally subject to them, either in the membranous or the ulcerative form, and to make specific affections of each of these shades would be folly.

These inflammations once commenced, the mucous membranes are presented in a state of redness or tumefaction. The gums are the most ordinary seat of them, as is also the palate, particularly when they possess a purely inflammatory character, and are allied to plethora, or owing to the suppression of an hemorrhage, &c.; the sanguineous disposition being then pronounced, no ulcerations occur. When the affection is especially owing to cold and local stimulations that have excited the mucous secretions for a considerable time, false membranes edged by a small white rim are frequently formed. The morbid process sometimes goes on to the destruction of the gums, and generates at the root of the teeth (which turn black) a collection of saline matters. Such an inflammation is frequently observed in barracks, where it may be contagious, and where it has got the name of scorbutic gangrene, though no disposition to scurvy then exists; this it is that M. Bretonneau had in view in his treatise on diphtheritis; he even makes use of the word "fegarite" in speaking of it, a word that is not Spanish, but derived from the Greek and Arabian, and which was first coined by Arnaud de Montgarni, a physician of the French army at Madrid during Napoleon's war there. Arnaud thought this disease was contagious, and as at that time they treated it with stimulants that set the mouth bleeding, and there were some serious symptoms, such as sloughing of the gums, luxation of the teeth, &c., he called it scorbutic; meantime it was only a gingivitis badly treated, with excoriation and ulceration of the gums, swelling and bleeding of the parts, fetid white exudation, putrescence and de-

composition of the humours and tissues. But there was no reason for calling this scorbutic; for the same parts in an inflamed and superstimulated condition might undergo similar changes any where—in Paris as well as in Madrid; I often meet it here in men treated as above stated. This is the first form of gingivitis.

A second form is the aphthous, which is more frequently consecutive than the preceding one, but which also may be primary, for I have seen it so; I have even seen persons whose mouths were filled with aphthæ and the mucous membrane considerably swelled, without the predominance of these symptoms in the gums: at the same time there was a copious salivation, which is not always met with in pure and simple gingivitis. This kind of thrush has such relation to mercurial phlegmasia, that I might have combined them in one description, did not the latter belong to another section of our plan, and if it were not moreover distinct, by having no fixed duration, and the possibility of its persisting, notwithstanding all kinds of treatment, so long as its cause continues, and of producing necrosis; whereas, by treating aphthæ by demulcents we cure them.

Patients labouring under gingivitis suffer from thirst, though seldom to the extent of producing fever. If you stimulate inopportunely, it may be succeeded by gangrenous spots, or a purulent collection about the gums, and be propagated to the pharynx and viscera. It is then arrested with great difficulty, as is indeed every inflammation treated improperly in its commencement; particularly if it be situated in organs that are exposed to the frequent contact of external bodies, as in the present instance, where the physician and the patient may, according to their taste and false inspiration, stimulate to the first, the second, or the tenth degree. Thus stimulated, it would be an arbitrary stretch to attempt to assign it a determinate progress: but when not stimulated, it lasts pretty nearly the usual time of mucous inflammations—fifteen to thirty days—and then gets well, after more or less salivation. After it has continued for a considerable period, and has caused atrophy of the gums, the teeth become uncovered, consumed by caries, and liable to fall out in consequence of the ingress of the inflammation into the alveolæ, and the final destruction of their pulpy membrane by suppuration; the teeth, then only holding by the small dental vessels and nerves, loosen and fall out.

There is also a phlegmasia of the gums which dentists consider to be incurable, and which consists in a softened condition of their tissue, with suppuration and fistule: I shall afterwards state my mode of treating this condition.

As regards propagation of gingivitis to the

viscera, it is never seen except when the disease has been improperly treated.

The prognosis bears relation to its duration. When recent it is easily cured, but there is great tendency to relapse. When it has lasted long, has disorganized, or propagated, its importance is meted by the degrees of propagation and disorganization. Persons with pale gums and sound teeth are less subject to it than others. The main point is not to consider the disease as something fatal, or as a pestiferous ray from heaven that strikes indiscriminately.

The treatment is easily comprehended, and is reducible to four principal points.—

1. When the inflammation is considerable, an immediate relief must be given by bleeding, if there be plethora or a congestive state of the head, or by leeches, if the disease be circumscribed, applied externally, or internally; the latter being preferable.
2. After these means come emollient gargles.
3. After these, the withdrawal of solid food and all kind of stimulation that can keep up the disease. At Val-de-Grâce, we put our patients on soup diet, apply leeches around the jaws or lips, or else internally, and make them gargle with decoction of marsh-mallow.
4. When the inflammation has abated, when there is no more heat, but only a habit of secretion, with sponginess, stimulation, or what they call counter-stimulation, may be employed. Then it is that narcotic and astringent washes, muriatic or nitric acid gargles, or those of the chlorurets, styptic salts, superficial cauterization with alum, or nitrate of silver, may prove useful, and speedily accomplish a cure. Have a care to observe well the effects of your remedies, your washes, gargles, &c., diluting if they stimulate too much, augmenting if they do not irritate sufficiently; in short, proportioning the stimulation to the sluggishness or inactivity of the diseased tissues. Bear one fact in mind, that when inflammation has been combatted by antiphlogistics, and still persists, it will tolerate direct stimulation. If there is continuous salivation, we persist in alternately narcotic and detersive gargles, we cause revulsion to the extremities by keeping them warm, we purge if the digestive canal is in good condition for it. Let me ask, in passing, what more we do in mercurial affections of the mouth? Nothing more.

We come to the phlegmasiæ of the isthmus of the throat, and of the velum palati—of the tonsils particularly. The inflammation of these parts is tonsillo-staphylitis, which is exhibited in two forms; one inflammatory without supersecretion, purely membranous or phlegmonous, the other exudative. Let us first consider the former, the highest degree of which is acute amygdalitis, or quinsy. For causes, it has all those that are capable of producing plethora and inflam-

matory affections, such as the suppression of certain evacuations, and especially of hemorrhages. Its predispositions are youth, the sanguine temperament, stimulating and too nutritious diet, producing blood that is either too copious in quantity, or stimulating in quality. It often co-exists with a heated state of the stomach, which is not inflammation, though so near to it, that the slightest thing will make it commence. The exciting causes are also stimulating causes, and they produce their effects when the patient can no longer bear stimulation: a sudden cold of the feet or head, a fit of impatience or anger, the suppression of an hemorrhage, in fact, anything that gives the system a stimulating shock more energetic than usual, determines an inflammatory amygdalitis.

This disease is readily known by the rapid and excessive swelling of the tonsils, which form a tumour and sometimes grow to such a size as to proceed backwards and downwards into the pharynx, depress the glottis, and in a short time render the respiration laborious and the voice nasal. The countenance is anxious: dissemination of the irritation by the nerves is carried to a great extent, the fever is sharp, the pulse full and frequent, the heat exalted, the skin halituous: the acute pains in the throat render deglutition exceedingly painful, inducing contorted, or even convulsive movements at the time of swallowing. On depressing the tongue we observe the tonsil red and swollen, and nausea is readily produced; the mouth is opened with great difficulty and pain; a *speculum oris* may be used for the purpose of assisting its opening. The consequences of this kind of angina may be serious; the most serious of all is that when the tonsillary swelling is such as to make them fill the entire cavity of the pharynx, press down the epiglottis upon the glottis until suffocation takes place: cases are met with in which this might readily occur, so rapid is the increase of the swelling and the dyspnoea; the patient is then obliged to open wide his mouth in order to breathe, and the face becomes livid.

There are other shades in which the tonsils stop swelling at a certain point and does not interfere with respiration; in these cases it often goes on to suppuration. It may happen however, that while one tonsil is suppurating the other goes on swelling—a thing that sometimes happens in individuals that have had several attacks of quinsy, who are of a lymphatic constitution and whose tonsils were already gorged and enlarged, on the advent of the acute inflammation. For the rest, death can only occur from suffocation; for when the phlegmasia goes on to suppuration, no fatal termination can take place. After being in the back of the throat it may certainly, if not arrested, extend to the viscera and become predominant then: but that is a general fact that

applies to all inflammations whatever. The danger is from suffocation, and the prognosis should be directed by the degree of tonsillary tumefaction; if they feel large to the finger, extending down to the throat, if the patient is restless, gasps for breath, and is at times seized with convulsive movements, and has swelling of and livid face, the peril of his position cannot be mistaken. We next proceed to the treatment.

MANUAL OF OPERATIVE MEDICINE,

BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

—

CHAP. V.—OF REUNION.

THE wounds which result from operations are sometimes left to suppurate; sometimes attempts are made to unite them by the first intention. In the latter case, position, bandages, agglutinative plaisters, and sutures are employed. The two first of these do not form part of our subject*.

SECT. I. *Agglutinative Plaisters*.—Some are applied cold; others require to be softened by heat, over a candle or brazier. The English silk sticking-plaister requires to be first moistened with saliva.

In the *ordinary mode* of proceeding, the borders of the wound being approximated by an assistant, the surgeon begins by placing a strip of plaister on one side; then supporting the opposite border of the wound himself, he applies the strip, well stretched, to this other side, keeping it on the point which is most remote from the division. It is very requisite that the skin be cleaned and perfectly dried. In M. Gama's mode of proceeding, strips of plaister are cut off at least an inch in thickness, and long enough to pass twice round the limb or trunk, or at least the part where the wound is situated. Each strip is rolled into two rollers. The centre of these is placed on the point diametrically opposite to the wound, and each end drawn towards the wound, the borders of which may be thus brought together with any degree of force. The ends of the strip having been crossed, they are passed round the limb a second time. This method is superior to the other; it secures an exact, firm, and irretractable adaptation of the lips of the wound, and is less liable to produce strangulation of the parts, or to permit relaxation of

* It would be difficult to say why; however, the different positions and bandages which contribute to reunion, will be noticed in the accounts of particular operations.—T.

the dressings. If necessary, openings may be left between the strips of plaister, to apply lotions or leeches. If there is reason to fear pressure on the arterial trunks, this may be removed by placing compresses or charpie along the sides of their course. After three weeks or a month, the apparatus is removed and cicatrization is complete.

The ancients had a method now abandoned, which they called *dry suture*. It consisted in placing long strips of plaister on the sides of the wound and parallel to its direction, and sticking them together. Roux sometimes in this way makes eyelet-holes in the plaisters, passes a thread through them and thus draws the edges of the wound together in the manner in which stays are laced.

Of Sutures properly so called, or Bleeding Sutures.—Before the reform which took place in the eighteenth century, there were reckoned from fifteen to twenty kinds of sutures for wounds of the integuments. At present we retain only four, which might be reduced very well to two.

The following are the *general rules* for sutures; 1, the wound ought to be well washed, &c.; 2, the different points of the lips of the wound should be made to correspond exactly; 3, the integuments should be penetrated at an angle of forty-five deg. at least; if traversed more obliquely, a portion will be embraced at once too thin and too broad; 4, the thread ought to penetrate so deeply into the wound as not to leave beneath it a space in which pus may collect; 5, we should avoid pricking nerves, membranes, or tendons; 6, if the needle is passed from without inwards, the flap should be held between the thumb and forefinger of the left hand; if from within outwards, these two fingers are to be pressed on each side of the line through which the needle is to pass; 7, when suppuration is expected, a free space must be left at the bottom of the wound, to receive a piece of charpie; 8, the distance between the points may vary according to the thickness of the flesh; generally they should be close enough to prevent the wound from gaping in the intervals between them; 9, the distance between the edges of the wound and the points at which the needles are brought out, varies also. It ought not to be more than four lines, nor less than a line and a half, and should be equal on both sides; 10, it is usual to commence fixing the threads in the middle of the wound, except when this presents angles or passes across a free edge, as in the lip; in which cases the first suture is either made at the angles or at the free border; 11, the threads are not to be tied until they are all inserted, and either those in the middle or those at the angles should be tied first. The edges of the wound should be supported by assistants, until the last knot is tied; 12, the knots ought always to

be tied on the side of the wound, and as far from it as possible. They should be placed on the highest side of the wound in order to prevent their becoming saturated with pus: 13, it is an essential precaution to tie the knots so tightly as to close the wound, but not so tightly that when inflammation supervenes, the thread should strangle and cut through the tissues; 14, when a suture is made on a fresh wound, it may be left untouched for four or eight days. If the union is made by the second intention, the suture may remain applied for a month or more; 15, the threads are to be removed one at a time, and those are to be commenced with which are least essential, namely, those inserted last. The knot being cut with the scissors, the edges of the wound supported by an assistant, the thread is to be brought out from left to right, the left thumb and forefinger being placed around the point from whence it is to be withdrawn. We judge by the adhesion of the wound at this point, if we may take out the remaining stitches or if it be necessary to wait longer.

The *particular kinds* of sutures are—

1. *The Interrupted Suture.*—As many threads are prepared as it is proposed to make punctures. Each thread is passed through two curved needles. The first needle, held like a pen in writing, is carried down to the bottom of the wound and then passed through in a direction from within outwards, at a convenient distance. The second needle is passed through the other side in the same way. The needles are removed, and the ends of the ligature tied together, either in a double knot or in a single knot and a bow; the knot to be applied so as not to touch the cut surface. One needle only may be used; we commence by perforating one edge of the wound from without inwards, and then traverse the other side from within outwards. In employing *Lafaye's* method, we thread a single needle. The lips of the wound being held together by an assistant, we pass the needle and thread through both of them at once, and continue this backwards and forwards, leaving a sufficiently-sized loop of thread between each puncture. Then the loops are to be cut through and the sutures tied separately, beginning with the midmost. A third method (*Lavaugyon's*) serves to unite the three edges of a T incision. A thread with two needles is employed. One of them is plunged from without inwards at each of the angles, so that the loop of thread may be used to draw them together. Then both needles are carried from within outwards, beyond the transverse incision, and the two ends of the threads are tied in a knot. For uniting a cross-shaped incision, the method is of course the same.

2. *The Suture of Pelletier.*—This procedure is identical with that of *Lafaye's* for the interrupted suture, except that the

loops of thread are not cut, but are all rendered tight by pulling the two extremities of the ligature at each end of the wound.

3. *The Quilled Suture.*—It is practised like the interrupted, only the thread with which the needles are furnished is doubled, so that one of its extremities forms a loop. All the punctures being made, each end of the ligatures is to be undoubled, and across all the loops placed on the same side, and on the same line, a piece of bougie, the quill of a pen, or a roll of adhesive plaister is to be passed parallel to the wound. On the other side the threads are to be unfolded and tied on a similar substance, with sufficient force to close the wound. Some advise that the quills themselves should be farther united by ligature, but the custom is disused.

4. *The Twisted Suture.*—It is made with straight, round, gold or silver needles, or even common pins, which are left to remain where they have been placed. One of the needles is to be taken between the thumb and middle finger of the right hand, the index pressed upon its head, and the lips of the wound are to be brought into exact apposition. This needle is to be plunged into the sides of the wound, a line and a half or two lines from the divided edge, at first from without inward, through the first, then from within outward, through the second. The first needle being placed, a loop of thread is passed under its extremities, and the ends given to an assistant, who exerts a gentle traction. With the same precaution a second, third, or more needles are passed, and then the operator, taking the ends of the thread from his assistant, passes them in front of the first, and around its ends, to form a figure of eight; this he does four or five times on the first needle, and then proceeds to pass the ligature in the same way under the ends of the next, and so on until he arrives at the last needle, when he ties a knot. There remains only now to protect the skin from the points of the needles, which may be done by a soft compress. Some advise cutting off their ends with strong scissors; but it is better to use cylindrical needles mounted with a spear-shaped steel point, which can easily be removed.

In estimating the value of these methods, the method of Pelletier tends to pucker the edges of the wounds, and may always be superseded by the interrupted suture. The twisted suture is much less liable to cut through the flesh than any other. The quilled suture unites the bottom of the wound well, but causes the lips to gape. We reject it in all cases, and supply its place by the following modification of the interrupted suture. Before tying the threads, we place between them a graduated compress as broad as the space between the entrance and the exit of the needles, or a piece of plaster many times folded. Then the threads are to be tied upon this interposed substance, in bow-ties; by the

use of which we may, if the inflammation be violent, loosen the thread at pleasure.

SECT. II.—Of General Operations.

CHAP. I.—COMMON OPERATIONS, OR MINOR SURGERY.

Minor surgery, independently of the application of bandages, comprehends four kinds of operations: bleeding, counter-irritation, vaccination, and acupuncture.

Bleedings are made from the capillary vessels, by leeches, scarifications, and cupping; from the veins, by incisions of different kinds, from the arteries, by arteriotomy.

1. *In applying leeches*, it is advised to wash the part, and moisten it with milk, or blood, and to roll the leeches, until they are dry, in a cloth. They are after taken one by one between the finger and thumb, and applied by the buccal extremities, but the proceeding is tedious. In cavities of much depth, they should be applied through a speculum, which may be open at its extremity, or closed there, and open at any part of the sides where we may wish to apply them. Thus a speculum open in *front* is convenient to apply leeches to the prostate through the rectum (Amussat), one open at the end, for leeching the neck of the uterus. In a cavity where the speculum is inapplicable, as in the mouth, each leech may be placed in a glass tube, and pushed from behind the point to be bitten, by a pencil, or something of that kind. To apply leeches in considerable number, and over a large surface, it is common to put them in a large glass and turn that downwards on the skin; but many remain frequently at the bottom of the glass, or they all bite together closely, and render suppuration probable. It is better to place them in a cloth held in the palm of the hand, which may be reversed over them, and kept there to prevent them moving from under the cloth; or a glass placed over the cloth answers equally well. An instrument has been proposed (by Bouycers), called the *leech-placer* (*pose-sangsue*), it is merely a small case of fine silver thread, formed like an eye-glass, which is filled with leeches and then pressed with the finger on its apex firmly against the skin. The dullest leeches are said to bite. The explanation which is given of this is not very satisfactory, but the fact* deserves mention.

In applying leeches to the anus, Brunninghausen advises us to place in its orifice a piece of linen moistened with oil, to prevent their making their way into the bowels.

In order to get leeches off, we may pinch them, cut off their tails, put near their heads salt, ashes, or tobacco; but the best way is to insinuate the nail of the forefinger under their sucking extremity, and with a sudden effort twitch them off†. When leeches re-

* If it be a fact.

† The common objection is, that the teeth of the leech are sometimes broken off in the

main too long in the rectum, vagina, &c., or when they get into the stomach, injections of tobacco, wine, and nitre or common salt are advised. The last is the best. To *disgorge leeches*, some take them by the tail and draw them through the finger and thumb, so as to make them return all the blood they have swallowed. We have never seen them survive this process. When not wanted directly, it is better to allow them time to clear themselves in fresh water. If we wish to re-apply them soon, they may be powdered over with wood-ashes, a sure method of making them vomit. Some are usually destroyed, but the greater part are preserved. To restrain the bleeding after leeches, compression with agaric or powdered fibrin, or the use of the *argentum nitratum*, or what is better, of cobweb, usually succeed. Where the hemorrhage is very obstinate, a needle may be passed round the little wound, and the parts tied with a ligature. Auterhith fills the orifice with little bits of charpie, or uses a bit of split wood, with the fork of which he embraces the sides of the wound. The fixed forceps of Graefe or Amussat act on the same principles. Ridolfo di Tacco applies, with success, cupping-glasses over the bleeding part.

In order to make leeches bleed a long time, some have proposed to cut of their tails, and thus permit the blood to run for some time. But this experiment never succeeds: the leech falls off immediately.

2. *Scarifications* are of two kinds; simple punctures with the lancet (*mouchetures*), and scarifications properly so called, in which after puncture, incisions are drawn along the skin for an indefinite length. A bistoury is better. M. Larrey prefers a razor, cutting only on its rounded extremity.

In using the common or German scarificator, which disengages from 16 to 24 blades, it is only necessary to observe that it should be so firmly pressed against the skin as to prevent the elasticity of this structure from throwing them off, and so lightly as not to penetrate too deeply. This instrument is only used with cupping-glasses. The bistoury or the razor may be substituted in all cases, and is preferable when we wish to scarify a phlegmon, an inflamed stump (Larrey), gangrenous parts, &c.

3. *Of applying Cupping-glasses.*—In dry cuppings, we employ those retracted at their openings, or of a simple form, or even common drinking-glasses. The air they contain is rarefied by various processes, which cause such a vacuum that when the glass is pressed on the skin, this swells up and forms a prominent convexity. There are a number of methods of proceeding—1st. Pieces of paper, cotton, or tow, may be placed at the bottom

of the glass, kindled with a candle, and the glass applied to the skin. 2nd. The same substances, moistened with alcohol, may be used in the same way. 3rd. The German barbers merely plunge the cupping-glass in a pail of hot water, and apply it immediately. As the water runs out, the glass is filled with vapour, which is condensed in cooling. 4th. The English prefer warming the air contained in the glass, by means of the flame of a spirit lamp: the two latter methods have the advantage over the former, of securing the skin from being burnt. 5th. Some protect the skin with a piece of card upon which a small candle is lighted; but this is too complicated. 6th. Cupping-glasses surmounted by an exhausting syringe, are very certain and convenient, but are too dear to come into ordinary use*.

In all cases a flat surface should be chosen, any hair should be shaved, the glass should be held perpendicularly, to prevent the air getting in, and applied as soon as possible after the introduction of the flame.

In applying cupping with scarifications the means are the same, except that the glasses are to be applied for a few moments, as in dry cupping, previous to the scarification. When this has been done they are to be re-applied as frequently as the blood begins to coagulate.

Sarlandiere has invented an instrument (called a *Bdellomètre*) which is too complicated, however, but by means of which, when even once applied, the skin may be scarified and the blood drawn, without the apparatus requiring to be displaced.

—o—

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

(Continued from p. 86.)

Cerecloth and Winding-sheet.—These are destroyed much sooner when the body is not enclosed in a coffin. In this case, at the expiration of from twenty to forty days, the cerecloth is reduced to brown or black laminae, which are half rotten, some being easily detached, while others are so intimately blended with the earth and adherent to the body that they can only be removed by scraping pretty strongly with the scalpel, and large flakes of epidermis are detached along with them, firmly united to this mixture of earth and cerecloth. If the body has been buried in a coffin, the cerecloth becomes covered in many places with eggs, larvæ, and insects, and with the same sanies which we mentioned when speaking of the coffin; this brown pulp is found most plentifully on the back part of the body, and

wound, and give rise to irritation. I am not aware if this is ever the case; at all events it is very unfrequent.—T.

* To which may be added that they do not keep long in order.

especially about the head, neck, and shoulders, and forms masses which are black like liquid pitch, or gray like purulent sanies mixed with the pitchy matter; sometimes they have the consistence and colour of wheel grease. The cerecloth is now easily torn, and is sometimes covered with white mould. As putrefaction advances, this cloth becomes detached in fragments of the colour of dung, or black, and generally covered with a bituminous-looking matter.

The *winding-sheet* at first assumes a yellow colour, with more or less of red in the parts which are in contact with the body; after a little while, its internal surface, especially where the corpse rests upon it, is covered with spots, or small patches, of various colour and thickness, generally soft, and sometimes nearly fluid—these often appear to consist of the altered epidermis; the exterior is covered at many points with a yellow or reddish glutinous matter, which has transuded and assumed the form of lenticular masses, stalactites, &c. At this time the consistence of the linen is not much altered, and some parts of it which have not been in immediate contact with the body, are still white. Later than this it is still entire, but changed in colour; its anterior part is yellow, which in some places is very deep, and spotted with black, except where it has been knotted over the head and under the feet; in these parts it remains white; its posterior portion, which is in contact with the bottom of the coffin, is much moister and more spotted with brown, deep yellow, or wine-lee colour, especially about the head. The exterior of the winding-sheet is often almost entirely covered with larvæ of a yellowish white colour, which are still alive, and give the linen a woolly appearance; the interior presents patches of a yellow mould in some places and a lining of blackish brown fatty matter in others; it contains also innumerable larvæ in active motion. It is already rotten, and tears very easily in certain parts; in others it adheres pretty strongly to the body, and here the epidermis has degenerated into soft and almost glutinous layers.

At a more advanced period nothing remains but some layers of larger or smaller size, enveloping different parts of the body; their colour is blackish brown, but they are so covered with white mould and reddish larvæ that their colour is not at first apparent, and their surface bears a resemblance to certain lichens: when these extraneous substances are removed the linen is moist, very easily torn, and impregnated with a greasy matter, from which it derives its brown colour.

Finally, all traces of the winding-sheet disappear; we found none about the body of Madame de Noresse, who was disinterred three years and five months after her death, while in another instance of exhumation seven years after interment, a portion of it was still remaining.

Having described the changes which the tissues undergo successively during their decomposition, it is of importance to determine whether these changes occur at fixed periods, or whether there be more or less variety in this respect.

It results from our own researches, and those of a great number of preceding authors, that bodies interred at the same time putrefy with different degrees of rapidity, some being completely reduced to skeletons when others are still entire or have scarcely begun to be decomposed. It will not be uninteresting to throw a glance over the principal causes of these diversities, whose examination will evince the impossibility of determining with precision the period of the death of an individual who has been interred for some time.

These causes relate particularly to the age, constitution, sex, state of leanness, or obesity, mutilation, or integrity of the body, to the nature and duration of the malady that has been fatal to the phenomena which have immediately preceded death, the suddenness or protraction of the act of dying, the period of inhumation, the depredations of certain insects on the surface of the body, the nature of the soil, the depth of the grave, the circumstances of the body being naked or clothed, enveloped in a winding-sheet or a cerecloth, the presence or absence of a coffin, the thickness of the coffin, and the material of which it is made, which may be deal, oak, of greater or less thickness, lead, &c., and, lastly, to atmospheric influences, such as temperature, moisture, &c. Let us severally examine these causes:—

Age.—Observation has incontestibly proved, that the bodies of very young children putrefy much sooner after interment than those of adults and old persons, all other circumstances being similar.

Constitution of the Individual.—Although the influence of constitution is not so easily determined as that of age, it is sufficiently established, that individuals of a given temperament, as the lymphatic, for example, buried under circumstances in all respects similar, putrefy at a different rate. Have we not seen subjects nearly of the same age, equally lean, having died of the same disease, say an epidemic, after having been ill nearly the same number of days, interred in coffins of the same wood and the same thickness, side by side, and each twenty-four hours after death; have we not seen these bodies putrefy so unequally, as to time, that, while one has been in the last stage of decomposition, another has scarcely begun to change? To what cause is such difference to be attributed but to diversity of *constitution* in the individuals?

Different constitutions have much influence in this respect, by reason of the different proportions of the animal fluids, and the greater or lesser density of the tissues, which accompany each.

Sex.—The predominance of the lymphatic temperament in females, and the presence of a greater quantity of fat in the subcutaneous cellular tissue, cause putrefaction to take place more rapidly in them, *ceteris paribus*, than in men.

State of Leanness or Obesity.—What has just been said relative to the sex, would lead us to expect that obesity favoured putrefaction after interment, and this has been demonstrated by experience—it has also been found, as we shall presently relate, that the quantity of fat influences the *kind* of decomposition which the body undergoes.

State of Mutilation or Integrity of the Body.—Observation has proved how much solutions of continuity of a certain extent favour the decomposition of dead bodies; it is also well known that contused and ecchymosed parts, in which blood is extravasated, putrefy very rapidly; consequently, when this state of parts is complicated with solution of continuity in the skin, as in the case of a contused wound, the destruction after death is still more speedy.

Foreign Medicine.

Present state of the Medico-Legal Doctrines concerning Insanity in Germany. By M. Taufflich.

(Continued from page 146.)

WE proceed to pass in successive review the phenomena, both physical and moral, which German authors have laid down as certain in those monomaniacs upon whom their observations were made, and then point out the value and importance which they consider to be due to those symptoms.

The individuals in whom they observed instinctive monomania were in general nervous, hysterical, or recently delivered females, hypochondriacal and epileptic males, and young persons of both sexes at the period of puberty. These persons almost always exhibited more or less decided derangement of the digestive functions, chiefly characterized by a variously costive condition of the bowels, with a sanguineous congestion about them, occasionally followed by hemorrhoidal tumours. To this primary derangement were added, in the majority of instances, more or less of habitual headache, symptoms of cerebral congestion, highly coloured face, suffused eyes, tinnitus aurium, giddiness, an agitated and uneasy state, palpitations, a sense of constriction in the epi-

gastric region, &c. These painful sensations were roused to a great degree at the mere sight or sole idea of the object of the monomania; the sight of any instrument that might serve a violent purpose, of a knife for instance, was often sufficient to develop the greater number of the phenomena above enumerated.

The disturbances in the psychological functions were not less worthy of remark. A melancholy of varied intensity frequently precedes the attacks; the patient is bewildered on finding himself pursued by sinister ideas of murder or fire, to the horrors of all which he is perfectly alive, but under the power of which he is in constant fear of falling. This depression sometimes finds vent in showers of tears, a phenomenon inexplicable to the bystanders, because they have no idea of the terrible contest that is distracting his mental faculties. Sometimes the patient has the sensation of a voice within commanding him to murder or to set on fire. Up to this point reason has maintained its empire—the criminal impulse is repelled with horror: the patient, feeling all the danger of his position, strives to render the enactment of his propensities impossible. For instance, a mother sends her child that she is suckling to other care than her own, in order to prevent an event which she above all others fears. And what is more remarkable, this very fear, far from obliterating, far from weakening the homicidal desires of the unhappy mother, appears, on the contrary, to give them renewed activity: it exasperates the tempest of the mind, and heats the imagination by incessantly recalling the attention to an object which it would be better to forget. Frequently the patients reason with themselves; they call to their aid all the activity of their intellectual functions in order to combat the miserable thought that pursues them, and disclose to their own eyes all the enormity of it. Some even at the foot of the altar beseech the Deity in fervent prayers to deliver them from the atrocious propensity that besets them: others seek in distractions, in varying walks and journeys, the means of striving against this horrible disorder.

Notwithstanding these well directed efforts, the disease sometimes goes on increasing, the murderous idea returns at every instant

with renewed force, and leaves no interval of quietude, thus making the struggle more and more dreadful. The patient, a prey to harrowing distress, has exhausted all her means of resistance—she knows not how next to act. A moment at length arrives in which her insupportable sensations must be got rid of at any price; should the object of her monomania be then presented to her, the mischief that ensues may be readily imagined. The ferocious instinct, which neither reason nor religion, nor maternal love, has been able to prevent the growth of, ceases to be at all mastered in this moment of aberration and agitation, wherein even the shade of reflexion is banished, and if the physical means of gratifying her desires be not offered to her, the most dreadful excitement follows.

Such is the melancholy but true picture of the disease, as copied from facts observed in Germany, and it will be found not to differ from the same in other countries. The limits of this essay do not allow me to enter in detail into the observations that would justify the above description: I shall only relate the following case, which is particularly remarkable from the evident connexion that was found in the patient between certain bodily affections, and the attack of monomania. I quote it with confidence, as it is given by one of the most celebrated of the German medical jurists, M. Wildberg*, under whose actual observation it fell.

A man of erudition and great worth, who died not long ago, observed in himself the birth of an inconceivable desire to murder his eldest daughter. He was a man of 51 years of age, short compact stature, of a bilioso-nervous temperament; his face was naturally highly coloured; from the virile epoch he had been frequently visited by divers abdominal affections, constipations, hemorrhoids, by sanguineous congestion in the head, and frequent headaches; all which were accompanied by great mental depression, which was in great contrast with his gay disposition when in health. This tendency to hypochondriasm was increased and kept up by various vexations that he suffered about the time of these attacks. Gradually his mind became so affected as to render

painful and tedious to him the literary occupation in which he had formerly delighted, and he sometimes was so much a prey to anxiety, that he knew not what to do to procure ease. His eldest daughter, 17 years of age, had hitherto succeeded in relieving him from some part of his melancholy, and for this purpose was frequently with him in his study and his walks. One day she entered his apartment at a time when he was racked by sinister and melancholy thoughts. On a sudden the horrid thought entered his head of killing his child; he was so horrified at it that he begged her to leave him alone and that immediately. She was no sooner gone than he burst into tears, and was a long time of recovering from the violence of the emotion: subsequently he resolved to try the effects of change, and on the following morning he left his home and remained from it five days. During this journey his black ideas were in great measure dissipated; but no sooner did he again see his daughter than his homicidal desires were renewed with double force, and this every time he saw her, although as a man of pious habits and paternal feelings, nothing could be more abhorrent to him. From that time he caused everything that could assist in acts of violence to be kept out of his way, and at the same time took the precaution of never being alone with his daughter; notwithstanding which the horrible thought of destruction incessantly tormented him. Having consulted M. Wildberg on his case, the latter first of all insisted on the absence of his daughter for a period: he then subjected his patient to a gently purgative and antispasmodic treatment, recommending him at the same time to take frequent walks with a few friends; and this treatment effected a total change in the space of a fortnight. After a certain number of copious alvine evacuations the appetite returned, the sleep became more calm, his movements were more free, and the mind was visibly more quiet. He again began to have a taste for his usual occupations, with which he had been hitherto disgusted. Yet it was observed that in the company of his friends he every now and then became suddenly silent, would go to the window for a few minutes, and then as suddenly return to the conversation. The treatment was continued for a fortnight

* *Magazin für die gerichtl. Arzn.* 1831.

longer, and was closed by the administration of some tonics; the recovery was then complete, the patient feeling himself altogether and permanently rid of the sinister ideas that had tormented him. He desired to see his daughter, and from that time to his death never had a thought but for her welfare. M. Wildberg remarks, that had a similar state been present in a man of little or no education, he would almost inevitably have been drawn into the most confirmed homicidal monomania.

Remains to examine the state of the monomaniac immediately after the act of violence committed during the attack; this state should not be lost sight of, being allied to very important medico-legal considerations. But previous to addressing myself to this subject, it should be remarked that though the existence of *instinctive* homicidal monomania as above described has been frequently observed in Germany, the disease has rarely been known to lead to actual murder. In the majority of the cases of homicide committed in monomaniac paroxysms that appear in the works of authors, the patients were led on by a real partial delirium, originating in a false and absurd idea—they were in fact cases of *rational* monomania, and we shall return to them hereafter. On the other hand, incendiary monomania has very frequently induced to the actual commission of the act; and here I speak only of the purely instinctive monomania, that is to say, of the monomania that is characterised by the total absence of any motive whatever, reasonable or unreasonable. It will, therefore, be from facts connected with this latter variety of monomania, that I shall endeavour to trace the condition of patients immediately or very shortly after the deplorable act that would seem to assimilate them to the greatest miscreants.

Scarcely is the act finished than a perfect calm succeeds the violent agitation above mentioned; the terrible struggle that shook the subject to his centre, ceases with the impulse that had provoked and maintained it. At the time the patient feels himself actually relieved; he even feels a cheerfulness that does not fall to the lot of men who have acted freely and from criminal motives. The youthful incendiary mentioned by

Klein in his *Annales Judiciaires*, felt a joy she had never before experienced, on beholding the fire break out, and found herself freed from a load of anxiety that had oppressed her for three days. But this sense of relief is soon changed into the most bitter of feelings; a few calm moments suffice to bring back reflexion, and draw the attention of the patients to the deplorable effects of their action; and rousing as if from a deep sleep of mind, they recognise all the horror of the crime they have committed. A young girl, noted for her retiring behaviour and mild disposition, made seven successive attempts at incendiarism in her own village in the neighbourhood of Coblenz. Interrogated as to her motives to the act she wept bitterly, and said that at certain times her reason seemed to be deranged, and she was then irresistibly, and without any feeling of hatred, driven to the commission of the act, after which however she always suffered the most pungent remorse; still she persisted in saying in her justification, that whatever horror she afterwards felt, she could not do otherwise in her disturbed moments. On her trial, by the jury of Coblenz, Doctors Settegast and Ulrich readily evidenced to the existence of a mental lesion that deprived her of moral liberty at the time of the act, and she was unanimously acquitted. A distinction must therefore be drawn between the condition of these monomaniacs, and those that are so *by partial delirium*, who so far from agreeing in the criminality of their actions, imagine they have done a thing not only allowed, but useful and necessary.

We have now to examine, with the German authors, the value of the signs that distinguish true instinctive monomania from the mental condition of a man who, though urged by criminal desires, is not however deprived of his liberty—a task requiring much care, and, I fear, a greater number of observations than I have been enabled to collect. I shall, however, endeavour to bring together some data that may assist in determining the value of the signs of monomania, by presenting, in the shape of a summary, the practical conclusions that have been arrived at, or that may naturally be deduced from a certain number of medico-legal observations made in Ger-

many at different periods, but more particularly in latter years.

1. *The age and sex* are generally taken in considerable account, particularly in youthful incendiaries at the period of puberty. Both individual physicians, and whole faculties, have laid stress on this circumstance in enumerating the reasons for admitting a privation of moral liberty in those persons. If however the age of the sexual development be too readily admitted as an excuse, do we not expose ourselves to the error of establishing a relation of causality where only a mere fortuitous coincidence exists? And would not such errors tend to encourage crime? Might not, for instance, evil disposed men, in order to avoid retribution, make use of young persons in the execution of their designs, whose age would give colour to the pretext of incendiary monomania? These are questions that have been raised by several medical jurists. Amelung and Henke are of opinion that any value attached to this kind of justification should be yielded with the greatest caution, and that it should be altogether withheld whenever apparent morbid phenomena failed to prove that this evolution of the genital organs had excited a marked influence on the nervous system in general, and on the cerebral functions in particular.

The London Medical

AND

Surgical Journal.

Saturday, September 5th, 1835.

IMPORTANCE OF COMPARATIVE ANATOMY.

SEVERAL studies which were formerly deemed only accessory to medicine, are now justly considered as essential. One, however, yet remains whose importance is not duly appreciated, namely *comparative anatomy*. If physiology be the basis of medicine, comparative anatomy must no longer be considered merely as a collateral branch of science, since nearly all that is satisfactorily known in physiology has been derived from an extended survey of the various

forms of organized being; and since, in the investigation of points that are still doubtful, we have reason to be daily more distrustful of the results of direct experiment on the living organism, and further encouraged to trace the connexion of certain functions with certain organs, by marking the increased perfection of the former, invariably accompanying the fuller expansion of the latter, and *vice versa* in a descending scale, the system of animated nature, if properly viewed, presents a grand series of those experiments which physiologists ineffectually institute by the barbarous mutilation of living animals. A physiologist, for instance, scoops out the brain of a cat, and proceeds to record the effects of this delicate operation on the *vital* phenomena—of what? *a dead cat*. Would he not be better occupied in observing the modifications of function which accompany the gradually curtailed development of the brain, from man down to the *mollusca*? In this series we find parts of the organ disappearing, and, if we go yet lower, to the *rudiate*, we find the whole disappearing, but all without *mutilation*; each of our subjects is an entire and healthy living animal, fulfilling, undisturbed, all the functions which nature intended it to perform—that is, it is a legitimate object of *physiology* which is the study of the natural and healthy functions of organized life.

In performing experiments which involve the fatal mutilation of animals, we are studying death, not life; we are learning the influence which the removal of an organ has in *killing* an animal, not the influence which its presence has in *keeping it alive*.

We do not at all wish to deny that the *clue* to many important discoveries may be found in such experiments, but we entirely agree with the greatest physiologist of this age—Sir Charles Bell—that the discoveries themselves must be the result of diligent anatomical investigation; and how can that inves-

tigation be so effectually pursued as by following each organ or system from its most rudimentary form to its highest perfection, or from its full development to its final evanescence?

Again, the study of comparative anatomy greatly facilitates the acquisition of human anatomy. By their conjunction the subject is viewed in its essence, apart from those dry, and frequently useless details, which now cost the student so much labour when at school, but which he afterwards finds so difficult to retain, and so little worth retaining; by the comparison of different modifications of organs ministering to the same function, anatomy becomes physiological instead of mechanical, and the student easily remembers that a thing is one way rather than another, because he sees a *reason* why it should be so.

We trust that in the approaching reorganization of the profession, the means of cultivating this most interesting and useful department of knowledge will not be neglected. We already possess—no we are wrong, *we* do not possess—but the Council of the College of Surgeons do—facilities for the study of comparative anatomy, not elsewhere to be found on earth; we allude to the Hunterian Museum: this inestimable collection will no doubt soon be rescued from the fraudulent gripe of its present self-constituted guardians, and it will then be a shame for the medical practitioners and students of this metropolis, if they fail to profit by such splendid opportunities.

The establishment of a chair of comparative anatomy, in connexion with the Museum, would be attended with great advantages, and, in the event of one faculty being immediately instituted, we have little doubt that such a professorship would forthwith be created. When the general intelligence of the profession is brought to bear on its institutions, the wise men now in office will soon see how much the *subordinates* are in advance of them, and how

rapidly the genuine light of science has been diffusing itself through the medical community for some years past, while *they* have been supinely slumbering in the unwholesome shade of corporate indolence.

—o—

FRENCH HOSPITAL STATISTICS.

—

IN all France there are 1,349 hospitals and infirmaries.

The arrangement of patients, during the year 1833, was as follows:—

Patients on the 1st of January - 154,253
Patients admitted during the year 425,049

Total of patients treated - 579,302

Of this number 381,169 were discharged, and 45,303 died, and 152,830 remained under treatment the 1st of January, 1834.

The ordinary and extraordinary revenues of France, in the year, were 51,222,063 francs, and the ordinary and extraordinary expenses 48,842,097 francs.

The annual average receipts of the hospitals, taken by departments, was 595,605 francs, the average expenses 567,931 francs. The two departments showing the maximum of receipts and expenditure are those of the Seine and Rhône: the Seine having 10,057,098 francs, and 10,054,225 francs expenditure; the Rhône, 2,380,293 francs receipts, and 2,325,496 francs expenditure.

Corsica has the smallest receipts and expenditure: the former being 44,335 francs, and the expenditure 42,380 francs.

—o—

PARISIAN HOSPITAL STATISTICS.

—

THERE are 12 hospitals in Paris:—these are, the Hôtel Dieu, contains 1000 beds. All kinds of patients are admitted except children, lunatics, incurables, lying-in-women, and venereal or chronic cases.

Hôpital de la Pitié, 600 beds; same diseases as the Hôtel Dieu.

Hôpital de la Charité, 300 beds; same diseases as the Hôtel Dieu.

Hôpital Saint-Antoine, 250 beds; same diseases as the Hôtel Dieu.

Hôpital Cochin, 200 beds; same as Hôtel Dieu.

Hôpital Necker, 140 beds; same as Hôtel

Dieu, with the addition of a special ward for cases of lithotripsy.

Hôpital Beaujou, 180 beds; same as the Hôtel Dieu.

Hôpital des Enfants, 550 beds; for children of both sexes, from five to fifteen years.

Hôpital Saint-Louis, 700 beds; skin diseases, ulcers, scrofula, &c. Gratuitous advice every day, medicinal, vapour, sulphur, and other baths.

Veneral Hospital, 650 beds.

Maison Royal de Santé, 175 beds; for the sick and wounded who are unable to get attendance at their own residence; here they pay three, four, or six francs a day for every thing.

Lying-in Hospital, 350 beds.

There are ten infirmaries, institutions, or asylums, namely:

Foundling Hospital, 258 beds.

Two infirmaries for the aged—for women, the Salpêtrière, 5,100 berths: for men, the Bicêtre, 3,200.

Two infirmaries for incurables: for women and children, 525 beds; for men, 455.

Hospice Laroche-focaud, 200 beds; a retreat for the servants of other infirmaries, the indigent, aged, or infirm, of both sexes.

Orphan Asylum, 750 beds; one half for girls, and the other for boys; these are maintained until they become of age.

Institution de Saint-Perine, 175 beds, for persons of both sexes, who pay a fixed sum for admission and board.

Hospice des Ménages, 670 beds, for indigent married people; the men must be at least 70, and the women 60 years old; widowers or widows 60 years.

Hospice Saint Michel, 12 beds, for septuagenarian men, founded by M. Boulard, a merchant of Paris.

There are, therefore, in all Paris, 16,540 beds for patients. Besides hospitals, there are in Paris a great number of other charitable institutions that are not included in the management of the general committee of hospitals.

Hospital Reports.

WESTMINSTER HOSPITAL.

Hydrophobia.

ON Saturday last, Dr. Burne, according to promise, made some remarks on the case of Hydrophobia, of which an account was given

in last week's journal. As it principally consisted in a recapitulation of the case and treatment adopted, we have only to supply any additional particulars since obtained, and a summary of the Doctor's remarks. It was learnt, on inquiry, that though the wound quickly healed, yet it remained tumefied and tender for some weeks. His son was also bitten by the same dog, whether before or afterwards was not known, but he has experienced no inconvenience from it. The dog, which was not his own, was shot some time afterwards on account of paralysis of the hinder extremities, supposed to be caused by being frequently thrown into the water: it evinced no hydrophobic symptoms whatever, previous to death. It was on the 20th, after four days' indisposition, that there was first an aversion to fluids; at breakfast he did not take his usual quantity of tea, nor did he touch any of the toast and water, which had been placed beside his bedside when he laid down, because he complained of thirst. He was that night excessively restless, spasm of the throat occasionally occurred, and there was excessive itching of the hand and arm, which he scratched violently in consequence. It was on the morning of the 21st, that the sight of fluid caused evident annoyance, and gave rise to spasms of the throat. After detailing the progress of the complaint, the treatment and the post mortem appearances, Dr. Burne proceeded to remark, that the disease was one of function, and not of organic lesion, and that the appearances found were to be regarded as effects and not as causes of the disease. The thorax muscles and the heart were found soft, which condition perhaps depended on their violent exertion. The fluidity of the blood could not be regarded as depending on embarrassed respiration, for in cases where it had been so most remarkably, the blood had coagulated very extensively, but in asphyxia caused by the inhalation of poisonous gases it was found fluid: in the present case, the fluid state of the blood might perhaps be ascribed to nervous influence. The collapsed state of the lungs was probably dependent on asthma, to which the man had for years been subject. Though the vascularity of the lining membrane was excessive, yet there was no change of structure. In fine, no cause of death could be constituted by any of the pathological conditions.

Dr. Burne stated that the disease might be latent for a space, varying from 14 days to 24 months: this case, therefore, came within the limits. No evidence existed of the rabidity of the dog. To the question, why the poison should lay dormant in the system as long as it does, Dr. Barry's answer affords perhaps the best solution: the bite of a dog causes a lacerated wound, by which the structures implicated are destroyed, and the poison remains in the wound: the process of healing now takes place, and as the organization of the part is restored, the poison is absorbed.

The following fact is corroborative of this position: a case of hydrophobia occurred after the bite of a cat, which terminated fatally in six days: now, the teeth of a cat are sharp, and would not cause a lacerated wound, so as to give rise to destruction of the structures implicated, and the poison therefore, as in this case, would take effect much more speedily. The spasm at the sight of water must not be considered an essential symptom in this disease: it is merely produced from association; the patient, knowing the effect produced by endeavouring to swallow, is easily affected by the bare idea of it, in his extreme state of irritability, which also gives rise to the effect produced by the application of air. The state of pulse is remarkably indicative of the progress of the disease. In referring to the treatment adopted, Dr. Burne said he had chosen belladonna, as being a remedy less tried than any other, and from observing its great efficacy in allaying the irritation concomitant with the sore throat of scarlatina. In this case, certainly, no benefit had been derived from its use; perhaps it had not been given sufficiently early: he should be desirous of giving it further trial when opportunity offered, administering it in large doses. In conclusion, Dr. Burne spoke slightly of the prophylactic treatment: excision should of course be performed immediately if possible, and suction is also a valuable means of preventing unpleasant consequences in all cases of poisoned wounds.

Fracture of the Parietal Bone of a newly-born Infant, &c. Death—Autopsy.

A dead infant was found on Wednesday, August 19th, in St. James's Park, and was brought to the hospital; it had a shirt tied around it, and was wrapped up in an apron. By request of the coroner, the body was examined on Thursday, by Dr. Basham, clinical assistant to the hospital.

The following appearances were met with. The external surface presented no marks of injury, with the exception of a bruise or two on the left cheek and hip, the largest of which was about the size of a shilling. The umbilical cord had been divided about nine inches from the navel, and had not been tied, at least there was no ligature upon it when brought to the hospital. The surface of the abdomen, and the neck, presented the green and livid appearances characteristic of incipient decomposition.

Over the left parietal bone there was a considerable tumefaction, but there was no mark of violence on the integuments, in the shape of a bruise, &c. Upon dividing the scalp, the tumefaction was found to depend upon a quantity of dark coagulated blood under the aponeurosis of the occipito-frontalis muscle, which extended over the left half of the roof of the cranium, being most abundant over the parietal protuberance. Upon exploring the left parietal bone, it was found frac-

tured in two places: one fracture extended from the protuberance to the sagittal suture, the other, a smaller one, from nearly the same point to the lambdoidal suture. The calvarium being removed, a considerable quantity of coagulated blood was met with on the surface of the brain generally, and more especially in the situation corresponding to the fractured bone, it was seated between the arachnoid and pia mater. The brain was in a state of extreme softening; its vascularity, however, might be regarded as nearly normal. At the base of the cranium, and in the spinal canal, the arachnoid sac contained a rather abundant quantity of bloody serum.

The lungs were found in a half-collapsed state, and crepitated to the touch, and shewed the presence of air in them, through some of the semi-transparent superficial lobules. The pulmonary vessels contained a quantity of blood not coagulated. The lungs floated, upon being placed in a vessel containing water. That the gas contained in the lungs was atmospheric air, and did not result from the process of decomposition, appeared to be proved by the red and healthy appearance of these viscera, which did not present the least trace of putrefaction. The stomach was perfectly empty, and its mucous surface healthy. The small intestines contained a little gas. The large ones were distended with an abundance of dark green and viscid mæconium. The umbilical vein in the abdomen was highly distended with gas, doubtless arising from the decomposition of the umbilical cord; it resembled, very considerably, a portion of small intestine.

Notwithstanding the satisfactory nature of this evidence, establishing as it does the violent death of the child, it seems that on the inquest, the jury tendered a verdict of "accidental death." This would have been received, had not Dr. Basham remonstrated very strongly against so complete a neglect of his evidence, upon which, the coroner directed the jury to re-consider the subject, when they brought in a verdict of "wilful murder by some person or persons unknown."

—o—

FIFTH MEETING OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Anatomy and Medicine.—Mr. Hart read a 'Report on the action of certain poisons on the animal system,' drawn up by Dr. Roupell, at the request of the Association, at their last meeting. The section passed a vote of thanks to the learned gentleman for the care, accuracy and ability with which he had performed the task assigned him.

Dr. Alison read a paper, 'On the state of arteries leading to inflamed parts.' During the continuance of inflammation, the arterial capillaries were in a state of relaxation and distention, and unable to transmit forwards

the blood sent to them; and not only the capillaries, but also the larger arteries leading to them, were thus affected, having lost a portion of their contractile power, usually denominated tonicity. The latter position the learned professor endeavoured to prove by direct experiment; a portion of the axillary artery of a horse which had suffered from severe inflammation, was placed horizontally between a perpendicular column of mercury and a graduated tube containing water; the contractile power of the artery was made to expel a portion of the water, the quantity of which, as indicated by the graduated tube, was consequently a measure of the contracting power or tonicity of the artery, which was found to be in the artery of the diseased limb as compared with that of the sound one, as 10 to 16. Similar results were obtained from observation on the power of redilatation of the structures after their final contraction at the moment of death. The blood is in a state of accelerated motion towards the inflamed part; where it is retarded, the fibrine seems to be increased, with a stronger disposition to concretion or coagulation. From the previous considerations, the learned gentleman proposed the conclusion, that the increased vital action of the blood during inflammation, was not communicated by the coats of the vessels, but that its cause and seat must be sought in some other situation.

Dr. Alison next proposed to the section some interesting speculations on the power of atmospheric air in promoting the circulation, which he held to be otherwise than by its mechanical influence. On leaving a rabbit for some time in azote, and removing it before asphyxia had been completed, before even its respiration was much altered, he found, on destroying the animal instantly, that its circulation had been interfered with as completely as if it had been entirely asphyxiated; the right side of the heart was in strong action, but could not transmit the blood through the lungs. The learned gentleman answered some objections which might be urged from the contractile properties of the capillaries; in conclusion, he proposed the following speculation, that in the lower classes of animals, and in vegetables, the motion of the fluids may be promoted by the air otherwise than by interposition of its particles.

Mr. Whatton (of Manchester) read a most interesting paper 'On partial amputations of the foot.' After an admirably drawn up memoir on the former modes practised in France and England, and some strictures on those known as Chopart's and Hey's operations, in which, from the removal of the attachments of the tendons of the principal muscles of the leg, and the aponeuroses covering them, those muscles were rendered completely useless for the purposes of progression; and though the heel remained, the limb was scarcely so serviceable as a wooden leg. Mr. Whatton proposed and entered into a minute detail of the longitudinal operation which he had been

long in the habit of performing, and, as evidence of its complete success, and the advantages attending it, he presented to the section a patient on whom he had so operated. The man walked stoutly, without even a halt, could stand with ease on the imperfect foot, and seemed to suffer very slight inconvenience from the loss he had sustained, though, in this case, the three outer toes and metatarsal bones, the third cuneiform and cuboid bones, and a portion of the os calcis were removed. Mr. Whatton exhibited casts, taken from the foot at different periods after the operation, which, at the request of Professor Harrison, he presented to the Museum of the Royal College of Surgeons in Ireland.

Dr. Granville expressed his high admiration of the operation so admirably detailed, and proposed a resolution expressive of the particular approbation and thanks of the section, with a request that the author of it would not wait for the formal volume of the Transactions of the Association to publish such an admirable and useful operation, for the benefit of the profession and the community.

Mr. Carmichael, as the senior of the profession in Ireland present, begged leave to second the motion, and bore witness to the very inconvenient and almost useless condition of the limb after the transverse operation of Chopart had been performed; he did not hesitate to characterize Mr. Whatton's operation as one of the most important improvements introduced into modern surgery.

A member, although concurring in the justice of the resolution, feared the section would be going beyond its powers in passing such a resolution, for which he was not aware of any precedent. After some conversation, the resolution was agreed to.

Dr. William Stokes read a paper 'On certain thoracic diseases,' in which he endeavoured to establish unerring diagnostic marks, in cases where accumulations take place within the thorax from former diseases, which will seem to distinguish accumulations of air from emphysema of the lung, and accumulation of pus from pleuritis.

Dr. Evory Kennedy read a paper 'On the nature and treatment of purulent ophthalmia in new-born infants.' He detailed his treatment of this affection by strong solutions of lunar caustic. A conversation on the subject ensued, in which the plan was discussed by Drs. Beatty, Collins, Byrne, and Ireland. The latter gentleman threw considerable light on the subject, by explaining the chemical changes which take place in the nitrate of silver when it comes into contact with the animal matter on the surface of the eye, which cause it to lose its caustic properties, so that it mattered not whether the solution was made with ten grains or thirty, to the ounce of distilled water.

A paper was read from Mr. Knowles, of Birmingham, detailing a successful case of Cæsarian operation, from which the mother

had perfectly recovered, and both she and the infant were now doing remarkably well.

Dr. Corrigan read a paper on the peculiar sound frequently found in the heart, termed *Bruit de Soufflet*. He laid down a theory as to the efficient cause of this sound, deduced both from observation and experiment, and applicable to the different and even opposite conditions of the heart and great vessels in which it is known to exist. After showing that the causes assigned by Laennec and Williams were insufficient to account for all the cases in which it was known to occur, for instance, in both active and passive aneurism of the heart, in vessels of the pregnant womb, and in aneurismal varix, &c. &c., Dr. Corrigan explained his own theory by stating that this sound will be heard when, from any cause, the blood will flow through any cavity or vessel in what he termed "a current-like motion," that is, in different directions through a cavity too large for the entire mass; this he farther explained by representing the normal condition of the blood's motion to be that of an equably moving stream, flowing *en masse* without any diverging currents, and showed how conditions giving rise to this current-like motion existed in all these even opposite pathological states in which it was found. A conversation followed on this highly interesting subject, in which cases were related confirmatory to the views held by Dr. Corrigan, by Surgeon General Crampton, who was at this time in the chair, and Dr. Harty.

Dr. Perry, of Glasgow, read a paper 'On Typhus Fever,' in which he attempted to establish this disease as one of the exanthemata, produced by specific contagion, running a certain course, accompanied by its peculiar eruption, and ending in desquamation, at which time he observed it to be most capable of propagating itself by infection.

Mr. Le Strange exhibited the action of 'A new curved drill catheter' to the section, which, after being introduced with any required elevation or depression, could be firmly fixed to a table by means of a clamp to which it was attached, and the powerful action of the drill applied to perforate a calculus previously grasped by the instrument; this was found capable of breaking up calculi which resisted the action of the screw perforator, and the hammer.

Friday.—Dr. O'Brien read a paper containing his 'Views on the functions and diseases of the digestive organs.' These views, so important in their practical result, have been for some time before the medical public. Dr. O'Brien defended them most ably, before the section, from objections which had been made against them in some of the reviews shortly after their first publication.

Dr. Osborn, President of the College of Physicians, read a paper containing 'Observations on the effects of cold on the human body, and on a mode of measuring refrigera-

tion.' The great importance of this subject was shown by the fact, that from 57 cases of disease at present in Sir. P. Dunn's Hospital, 34 were distinctly traced to the application of cold.

From the great quantity of air (28 cubic feet every hour) which is being constantly raised during the process of respiration, to about 98 deg. Fahrenheit, at whatever temperature it may have been inspired, and from the well-known experiments of Sir B. Brodie in 1812, there appear good grounds for considering, besides its other important changes in the economy, that respiration is a cooling process; during health, very little effect is produced by the impression of atmospheric air on the bronchial surfaces, but it is far otherwise when the nervous energy of those surfaces becomes impaired, as occurs in chronic bronchitis, and low fevers; air reaching the ultimate air cells at a lower temperature than ordinary, causes an increase of torpor in the capillary system, and, they ceasing to contract on the blood, life becomes extinguished, and after death the right cavities of the heart and venous system are found gorged with blood. The learned president here made some valuable therapeutic deductions from the foregoing facts; he then took a review of the effects of cold on the mucous membrane of the stomach, which, though less sensible than other surfaces to different temperatures, was not exempt from the general law of diminished action following the continued application of cold.

But the most important effects of cold are visible when applied to the skin. The efforts of mankind to preserve a uniform temperature by clothing, habitations, and artificial heat, demonstrate the necessity of this uniform temperature to the comfort of our present state of existence.

Notwithstanding the great attention paid to the determining the actual state of the atmosphere as to its temperature, weight, and moisture, yet an important effect of its different states and conditions has been omitted, namely, *its cooling power estimated in reference to ourselves*. To supply this deficiency in atmospheric observation, Dr. Osborn took a spirit thermometer, without a frame, carefully graduated from 90 to 80 degs. inclusive, and having heated the bulb to 90, he exposed it to the cooling influences of different situations, and inferred that their refrigerating power was inversely as the time which was required to cause the descent from 90 to 80. The thermometer so applied, he called a psychometer, or measure of cooling, and suggested a number of circumstances to be attended to in order to secure uniformity of results. As a specimen of the modifications of the cooling power of the atmosphere, at the same, or nearly the same, temperature, he detailed the following observation—in open air, at night, temperature, 60, it cooled from 90 to 80 deg. in 3 m. at rest; in 1 m.

48 sec. in a slight breeze; at temperature 62 deg. it cooled from 90 to 80 in 3 m. 30 sec. at rest; ditto, ditto, 1m. agitated with arm.

The refrigerating power of water above air at the same temperature, is shown from the fact that at 70 deg. the instrument cooled from 90 to 80 in air, in 5 m. 40 sec.; in water at rest, same temperature in 24 sec.; in water, when agitated, 15 sec. Numerous important applications of this instrument were pointed out by the learned president, and, in conclusion, he hoped the subject would be taken up by some person who would have leisure to pursue the investigation, and in this event he hoped for some most valuable results on some of the abstrusest subjects connected with climate, and probably epidemics.

The communication excited much interest. After some observations from Dr. Clendenning, Dr. Granville proposed that a committee should be appointed, with Dr. Osborn at its head, to investigate the subject.

Dr. Hutton read an interesting paper containing a case of congenital malformation of left limbs upper and lower. There was no motion in elbow joint, and there existed congenital dislocation of the hip; both limbs were extremely atrophied. What rendered the case peculiarly interesting was, that on examining the head after death, the right hemisphere of the brain was found deficient in great part, its place being occupied by a distended cyst; the patient was idiotic.

Dr. Adams read a paper 'On Erectile Tumours,' in which he ably gave a sketch of all the forms assumed by that disease commonly called aneurism by anastomosis, and detailed some cases which had been successfully treated by seton. An interesting conversation ensued, in which the changes which occur in arteries, from the normal condition, was most ably and learnedly discussed by Drs. Crampton, Read, Handyside and Harrison.

A galvanic plaster was presented to the section; it consisted of powdered zinc and silver, firmly pasted on linen cloth, with a composition of shell lac and borax; the moisture on the surface of the skin was enough to excite slight galvanic action when it was applied; it had been used in America in cases of rheumatism and painful nervous affections.

Mr. W. S. Harris attempted to demonstrate the existence of bony union of the neck of the thigh bone after fracture, and produced for this purpose a portion of the femur and ilium of the late celebrated Mr. Mathews; but it was contended, after minute examination of the specimen, that the disease was not one of genuine fracture of the neck of the bone, but of an affection admirably described by Mr. R. W. Smith, of Dublin, under the title of *morbus coxæ senilis*; this opinion was chiefly insisted on by Drs. M Dowell and Collis.

Dr. Handyside (of Edinburgh) read a por-

tion of a paper, in which he experimentally examined the functions of the veins, lacteals, and absorbents in the animal economy; owing to the lateness of the hour, he could not conclude the subject; he referred the paper to the examination of the committee of the section. The business of the section having terminated, Professor Harrison proposed a vote of thanks to the strangers who had favoured the section by their communications.

Dr. Graves seconded the proposition, which was carried by acclamation.

Dr. Broughton being voted into the chair, vice Surgeon General Crampton, Professor Alison arose, and in the name of the medical strangers acknowledged the compliment, and begged, on their part, to return the Dublin medical profession their most sincere thanks, which was seconded by Dr. Granville. The resolution was carried *nem. con.*, and the section dissolved.

—o—

THE MEDICAL PROFESSION AS IT IS, AND AS IT OUGHT TO BE.

Mr. Dermott's Fourth Letter to George James Guthrie, Esq.

DEAR SIR—My last letter terminated with the consideration of the *two grades*. In apparent anticipation of the *superior* of those two grades, as advised by many of the Council of the College of Surgeons, the Apothecaries' Company have lately issued new regulations, establishing thereby a more extended Latin examination in Gregory and Celsus.

This forcing of men to learn the *dead languages*, by a long and tedious course of study, has done an immense deal of harm in the world—has engrossed the time of men and youths, and, in the same ratio, has retarded the progress of science, as well as political and moral knowledge, true, or living knowledge; in other words, a really sound education consists in acquiring a just perception of persons and things. Wisdom is the proper employment of that, in reference to circumstances or necessities, as they may arise. The very term *dead language* accuses itself—it means one which is *useless*. Sir Anthony Carlisle, who, although a conservative, and awfully mistaken on many points, very properly states—"The reading of Hippocrates, Galen, and Celsus, in the way of educating a physician, or a surgeon, is *perfectly absurd*. I believe that Hippocrates, Galen, or Celsus, would all be turned back in five minutes by either the College of Surgeons, or the Company of Apothecaries: since, if asked about the circulation of the blood, they would answer, that they never had heard of it." The same may be said of other Latin and Greek authors, in reference to other arts and sciences.

This accounts for the young men at Oxford and Cambridge being so deficient in all real knowledge—proving such mistaken dolts in politics—in ethics, as inseparably connected with the latter—and such ignorami as many of them are in anatomy and surgery, where they undergo the farce of attending a course of anatomy, consisting of four lectures in Lent term, and three in Michaelmas, most ceremoniously read, in a style, no doubt, well adapted for kid gloves; where the name of an examination is a “mere form*,” and not the reality exists; where a thesis is often procured by the candidates from the beadle, and where the beadle is the person to whom it is read; where it is often not known, six months before the time, whether the student is “to take out his degree” as doctor of medicine, law, or divinity!!! Before the *beadle* too!—witness, ye worthy doctors, the *dignity* of the medical profession! Do you seek *here*, Sir, for legal wisdom, medical knowledge, or pure, unsophisticated, unmammoned piety?

In answer to this, the farce of education carried on in them, the evil, political and moral effects which these institutions have in their present condition (as connected with the hereditary aristocracy, and the church and state business), the public know quite enough of to form a correct opinion. The whole time, or nearly so, of these students, is consumed in learning the dead languages.

But in behalf of this sort of *dead* education it may be argued, that the prescriptions are always written in Latin—that both medicines, and the parts of the human body, have Latin names. As to the prescriptions being written in Latin, this is only a part of the old system of mystification, which, in the dark ages, was used as a cloak to professional ignorance and empiricism, and had its influence over barbarians. The people at large are now so enlightened, that the relations of most of the sick, in private practice, expect to be informed as to the general nature of the complaint; and they are not only quite competent to receive an explanation as to the general principles which the medical man follows in his treatment, but they positively desire it: and, provided the medical man *can* give such a satisfactory explanation, it is the sure guarantee to his securing practice in the family afterwards, because he gains their confidence. But, on the other hand, the mystifying and reserved conduct amongst medical men, suits some who are bolstered up by family patronage uncommonly well; for it conceals error, and, in some surgical cases more especially, *murder*. The wording of the prescriptions, in Latin and hieroglyphics, has certainly this advantage, it

has furnished more work for the undertakers, for many patients have been dispatched, owing to mistakes in translating them being made by the dispensers.

In regard to the Latin nomenclatures of the medicines, and the various parts of the human body, I do not see the use of them, and I think the names would be quite as well, or better, in English; however, they are easily learnt by a person who is not a classical scholar. And as to Latin and Greek medical or philosophical authors, all those who are worth reading, and many more besides, have been translated long ago. Moreover, I consider that the occupation of translating ought to form a distinct profession of itself, for neither medical men, barristers, nor any persons of great philosophical research in their profession, can follow their practice, if extensive, and consume much of their time as well, in the dead languages.

I conceive that neither the College of Surgeons, Apothecaries' Company, nor any other medical body corporate, have any moral right to examine upon any thing but the branches of the profession and philosophical sciences connected with them; nor have they any moral right to inquire, Sir, *where* did you get your knowledge? Such is altogether a work of supererogation. You may as well go into a tradesman's shop, and say, Well, I find upon examination, your articles are very good, but I will not buy any of them, nor shall you have custom from others until you tell me where you got them, until you let me see your invoice, and I know the name of the manufacturer you received them of. It is quite sufficient that the candidate possesses the necessary knowledge; that must be ascertained by an undeviating mode of conducting the examination, i.e. the latter never must be adapted to the particular or accidental circumstances of individuals, for knowledge is the same to all. And if any class of examiners cannot, by mere dint of examination, and unaided by certificates or anything else, ascertain the degree of theoretical and practical knowledge possessed by a candidate (the subject being placed before him for anatomical demonstration, and his performing surgical operations), why then those examiners should go out to let others come in. It would, perhaps, be rather more arduous for the examiners, but the publicity of the examinations would ensure their efficiency. Certificates amount to nothing; for, granting that they are always correct as to the absolute attendance of pupils, a person may be often present at a lecture in person, but absent in mind.

My dear Sir, the College of Surgeons and Apothecaries' Company, in issuing of late such a multiplicity of regulations, have got deeper and deeper into the mire, deeper and deeper into the certificate system, which, as acknowledged by you all, does not work well—which in principle, in its operation, in its effects, is radically bad, and murderously

* See the Regius Professor's, Dr. Kidd's, evidence.

bad, and it will only make it necessary for the medical revolution, when the bill for medical reform is carried by parliament, to be more decided in its effects. Let it be understood, however, that the medical examination at Apothecaries' Hall is, as now conducted, admirable; or, at least, I believe as good as a *private* examination can be—quite equal to that at Edinburgh, and superior to those at most other colleges.

Believe me, my dear Sir,

Yours, very obediently,

G. D. DERMOTT.

Medical School, Gerrard Street, Soho.

Lectures Publication Bill.

A bill is now being passed to give lecturers the same copyright as authors. The principle is just, and will be adopted. The decision of Lord Eldon, that a lecture orally delivered might be published, because the lecturer could have no copyright in his words, unless written on paper, was one of the monstrous quibbles of our law and equity. It was the paper and ink that made the copyright, and not the substance and thought of the discourse. The legislature is, however, of a different opinion, and the new bill will give a man a right to his thoughts and brain, without his committing his lecture to paper.

A Parent of Two Children in Christ's Hospital School.

Our correspondent need not be alarmed; neither the almoners nor the medical officers will sanction the appointment of an inexperienced candidate. The appointment of a medical officer is of too much importance to be jobbed in the face of the press.

Death of Sir William Blizard.

Sir William Blizard, F.R.S., died last week in his 93rd year. A vacancy occurs in the Court of Examiners of the Royal College of Surgeons, which affords an opportunity to the Council to fill it in a more just and satisfactory manner than on the self-electing plan.

—o—

STATE OF THE MIND DURING DREAMS

DREAMS only occur in a state of slumber, or imperfect sleep; in deep sleep there is no dream. In dreams, the faculty of judgment being suspended, we have no control over the trains of images that arise in the mind. It is true that Drs. Reid and Beattie affirm that they persuaded themselves in their dreams they *were* dreaming; but it is thought they were labouring under incubus, with which state a degree of consciousness is compatible. The imagination having full sway during the state of slumber, dreams are frequently of the most extravagant character; every circumstance and subject on which the mind dwells

is exaggerated; fear becomes horror, and joy ecstasy. Scenery of the most gorgeous and splendid description is unfolded to us, and the mind revels in a world of its own. It is generally believed that dreams are universally the re-embodiment of thoughts and emotions that have at some period or other occupied the mind—they are old ideas new revived in an entire state, or heterogeneously mixed together. Dr. Mackish relates a most inconsistent dream which occurred to himself, which he was enabled, after considerable trouble, to trace to emotions and thoughts which had occupied his mind shortly before. We often find, too, that after meeting some friend or friends that we have not seen for many years, the mind dwells on them just before slumber, and the dream brings them to view, as we knew them in days gone by; the scenes with which that memory is connected—the haunts of our boyhood—the home of our infancy, comes before us again.

"Indulgent memory wakes, and lo! they live,
Clothed in far softer hues than light can give."

The circumstance of memory being in full activity during dreams, has given rise, in many instances, to a belief in supernatural visitations. Instances are recorded, in which communications have been made in dreams, relating to events which had apparently passed out of the mind and been forgotten. That of a bank clerk, related by Dr. Abercrombie, is of this character. On casting up his accounts at the end of the year, he found a deficit of ten pounds, nor could he, by every exertion of memory, remember to whom he had paid that sum. He went to bed thinking on the subject, when, in his dreams, the person to whom he had paid the money appeared. The dreamer had forgotten to register his name, in the hurry of business; on awaking in the morning, he perfectly remembered every circumstance connected with the event, and made his account correct. This occurrence is easily explained, when we remember the activity of memory during the state of dreaming.

Murderers have horrid dreams; Macbeth speaks of those horrid dreams

"Which shook him nightly,

When on the torture of the mind he lay
In restless ecstasy."

And the coward conscience of Richard speaks of the "shadows" that struck more terror to his soul, than "did the substance of ten thousand soldiers." Cromwell is said to have dreamt that he should be the greatest man in England; these probably arose from his mind being occupied, in its waking hours, with thoughts of self-aggrandizement and power; not from any divine meditation. Other dreams, of a similar character, may be accounted for in their being the re-embodiment of our thoughts and emotions of the mind.

LECTURES

ON THE

INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXVIII.

Motiferous Nerves—Muscular Motion.

VII.—The circumstances hitherto adduced afford presumptive evidence that the proper motiferous nerves and the motiferous portions of the regular nerves are the means by which volition is translated so as to act as a stimulus on the irritability of distant parts, but those still to be mentioned furnish conclusive evidence to this effect. It has been stated elsewhere that direct stimuli, mechanical or galvanic, applied to the trunks of the respiratory nerves, are found to excite certain actions which are usually sympathetic; but it is still more remarkably the case that such stimuli applied to the trunks of the nerves in question excite motions in parts, which, under ordinary circumstances, act only or chiefly in obedience to the will. Thus it has been abundantly established, that any such stimulus applied to the motor oculi, the motiferous portion of the lower maxillary branch of the trigeminus, the abductor, or the hypoglossal nerve, while it produces no indications whatever of pain or sensation of any kind, calls into spasmodic or convulsive motion the muscles which these nerves severally supply, and that a similar stimulus applied successively to the anterior or motiferous roots of the regular nerves, as they arise from the spinal cord, excites similar spasmodic or convulsive motions in the muscles to which these nerves respectively proceed, which succeed each other almost like the notes of a piano-forte on running the fingers in succession over the keys (*a*). A kind of gamut of this description—a melancholy one it is true—is sometimes run down by nature in tetanus, in which the successive occurrence of the gaping and fixed eye, the locked jaw, the elevated eyebrow, dilated nostril, and sardonic grin, the hurried and inarticulate speech, the rigid head, arched spine and stiffened limbs, corresponds almost precisely with the gradual extension of the disease along the roots of the motor oculi and abductor, the motiferous portion of the lower maxillary branch of the trigeminus, the motiferous department of the facial, the

(*a*) These facts have been established principally by Sir Charles Bell (Phil. Trans. 1821 and 1822), Magendie (Journ. de Physiol. 1822), Mayo (Anat. Comm. 1822), Foderè (Journ. de Physiol. 1823), and Bellingeri (An. Univ. di Med. 1824). "I struck," says Sir Charles Bell, "a rabbit behind the ear, so as to deprive it of sensibility by the concussion, and then exposed the spinal marrow. On irritating the posterior roots of the nerves I could perceive no motion consequent on any part of the muscular frame, but on irritating the anterior roots of the nerves, at each touch of the forceps, there was a corresponding motion of the muscles to which the nerve was distributed." This was one of the first experiments tending to establish the fact in ques-

tion, and such experiments have been frequently repeated since with similar results; although it is fair to acknowledge that they have not been equally successful in the hands of every body who has tried them, and some persons have accordingly denied the conclusions to be drawn from them, and even attributed to Bell, Magendie, and the rest, a deliberate intention to deceive. An accusation of this kind of course cannot be replied to at all; and that they could have been themselves deceived is impossible. Suffice it to say, that during a period of thirteen years after his first statement, Sir Charles Bell had found no reason to alter his opinion.—(Lecture read to the British Scientific Association assembled at Edinburgh in 1834).

hypoglossal, and the sub-occipital, cervical, dorsal, lumbar, and sacral nerves. Nothing can be more beautiful or satisfactory than this lesson, taught us by Nature, of the incorporation of these nerves into one system, the office of which is to excite muscles, the ordinary stimulus to the action of which is volition, and the total isolation of this system from the respiratory; since, while none of the reputedly voluntary muscles escape in this disease, none of those the natural stimulus to the action of which is sympathy and passion or instinct are affected, any further at least than these muscles obey likewise the stimulus of volition, and being thus supplied at the same time with respiratory and motiferous nerves, become involved in the affections of the latter.

VIII.—The last circumstance, and one equally conclusive as the preceding, in favour of this doctrine is the fact, that as any action ordinarily excited by sympathy and passion or instinct is intercepted by the division of the individual respiratory nerves, so any action commonly excited to volition is at once obviated by the division of the individual motiferous; and consequently, if the common root of this system be destroyed—as has occurred in some memorable cases of a decay of the anterior columns of the spinal cord—all such actions are of course for ever lost. To omit the effects resulting from injuries of the individual motiferous nerves, those of the impeded function of this system, in general, are beautifully illustrated by that form of palsy in which one side of the body no longer receives any stimulus from the motiferous nerves, and the contrast, therefore, which the so-called voluntary muscles on this side offer to those on the other is particularly striking. In this disease, when perfect, contrary to what occurs in tetanus, the upper eye-lid of the affected side is pendulous under every effort to raise it (*motor oculi*); the eye-ball is stationary, as far at least as volition is concerned, not, however, from excess, but from defect of stimulus (*motor oculi* and abductor); the jaw partially falls (motiferous portion of lower maxillary branch of trigeminus); the eye-brow sinks, the nostril is pinched, and the mouth, yielding on the diseased side, is drawn over to the other (motiferous department of facial), the speech is imperfect—again from defect, and not from excess of stimulus—and the tongue, when protruded from the mouth, tends to the diseased side, the *genio-glossus* of this side yielding to the action of that on the other, so that the point of the tongue is moved, as it were, upon a pivot (*hypoglossal*), the head also is turned towards the diseased side, from the yielding of the *sterno-clido-mastoid* muscle on this side to the action of its fellow; the spine, again, is curved towards the sound side, owing to the yielding of the muscles on the other; and the limbs of the affected side are flaccid and powerless (sub-occipital, cervical, dorsal, lumbar, and sacral). In the mean time, however, the action of all the muscles, the natural stimulus to which is sympathy and passion, or instinct, is quite unimpaired, except in as far as such muscles are liable to be acted upon likewise by volition, and, consequently from the change which they undergo from the lesion of their motiferous nerves, become less competent to act under the influence of their respiratory. No such change, however, occurs in those muscles which are furnished exclusively with respiratory nerves; nor does such a change always result from palsy, even in those which are furnished with both respiratory and motiferous nerves, as prevents altogether the display of sympathy and passion, or instinct, the shoulders, for example, as has been already mentioned, continuing to be raised by sympathy, when the respiration is obstructed, long after they have ceased to receive the stimulus in question.

The fact, then, appears to be established, that the proper motiferous nerves, and the motiferous portions of the regular nerves, in conjunction with such of the respiratory nerves as are furnished with motiferous filaments, are the channel by which the stimulus of volition is, by means of an intermediate action, conveyed to the organs on the irritability of which it acts as a stimulus, no reasonable objection having ever been offered to this opinion: and, with respect to the manner in which they so act as conduits of a direct or primary action in one part, so as to excite an indirect or secondary irritation elsewhere, nothing remains to be added to what was said respecting the operation of the respiratory nerves in a similar capacity.

These, then, are the two indirect or secondary stimuli to irritability—sympathy and passion or instinct, on the one hand, and volition on the other. Of these the former, as originating in any organ of the body, and acting on any organ, could not have been represented in the diagram already published, without confusion; but the latter, as originating always in the brain, and acting only on the irritability of the voluntary muscles, is represented in this diagram by the cord extending from the uppermost wheel to the small wheel—supposed to revolve on a pivot of its own—in the centre of the main or lowest wheel, and indicating, with this, the general faculty of irritability. The motion of this central small wheel indicates, it is true, one of the animal functions, and implies the previous motion, first of the main or lowest wheel, as moved by the horizontal train of cogs, then of that interposed between this and the uppermost wheel, and lastly of this uppermost wheel; the first step to voluntary motion being, as we shall find in future, that irritation, in which the organic functions consist, dependent principally on certain direct or primary stimuli, the second sensation, dependent on irritation, and the third, thought—in that mode of it which constitutes volition—dependent in like manner on sensation. It

was, nevertheless, proper to speak of voluntary motion in this place, since one of its immediate conditions is irritability, and it consists only in irritation—the laws of which we are now investigating; and it was in no degree necessary, as already observed, to enter at all into the conditions on which volition itself depends, in speaking of it merely as a stimulus to irritability.

Irritation, life, or living action, is the result of the mutual co-operation of more or fewer of the stimuli just enumerated and irritability or vitality; and it is in such irritation, modified according to the apparatus, or series of organs which displays it, that every primary and essential function of an organized being—respiration, circulation, deposition, absorption, assimilation, and generation—consists; and to these may be added, as consisting also in mere irritation, the function of voluntary motion, although this last is not, any more than sensation and thought, a primary and essential, but, as it were, an adventitious function, since it requires indirectly, as the two latter do directly, other vital properties besides irritability for its manifestation. Irritation, then, consists in primary vital action, sensible or molecular, modified according to the organ which displays it. We can, indeed, conceive irritation, or mere vital perception, to exist, as elsewhere stated, without any action whatever; but we can never recognise it otherwise than by such action, so that, for all tangible purposes, the two may be identified. But the only universally acknowledged instrument of vital action is the muscular fibre: it remains, therefore, a question of some interest to determine, in what manner this muscular fibre, under the application of a stimulus, is affected—in other words, what is the efficient cause of muscular motion.

The investigation of this question must be premised by the remark that all that we can pronounce *a priori* upon the subject is, that the muscular fibre undergoes in this case some physical change, since it is by such change alone that the mutual relations of the parts, solid or fluid, in contact with such fibre, can become altered; but whether this change consist in a shortening or elongation of itself, we are quite incapable of determining abstractedly, since either process is equally competent to explain the resulting phenomena. If a joint, for example, be held at rest, or a portion of fluid in a duct be kept stationary, by a certain balance being maintained between the length of those fibres which are inserted into the opposite surfaces of the one, or are situated on this and that side of the other, the former will be equally bent whether those fibres which are attached to one surface be shortened, so as to pull it, or those which are attached to the other be elongated so as to push it in this direction, and the latter will be equally urged forwards, whether the fibres behind it are constructed so as to act like a forcing pump, or those before it are dilated, so as to act like a sucking pump upon it. It was accordingly, in former times, a prevalent notion, that the physical change which the muscular fibre undergoes under stimulation was that of *active elongation*; and this notion has been adopted in modern times by some physiologists, with respect in particular to the sphincter muscles; that state of diminished length in which they are while closing the passages which they defend being regarded as their state of quiescence, while that state of elongation in which they are when these passages are open is looked upon as their action (*a*). Against this doctrine, however, as applied as well to the sphincters as to any other muscles, it seems sufficient to say that all are actually observed to become shortened, not elongated, under the operation of a stimulus, and that the sphincters obey the same laws in this respect as other muscles, may be inferred, among many other things, from what occurs in tetanus, on the one hand, and in palsy on the other; the sphincter ani, for example, being frequently so tightly constricted, in the former disease, as not to admit the smallest clyster-pipe, and so dilated in the latter as to be incompetent to restrain the natural discharges, whereas, had the active

(*a*) The idea of an active elongation of the muscular fibre, as constituting the proximate cause of muscular motion, seems to have been prevalent, at any rate, with respect to the sphincters, before the time of Galen, since we find him formally contending against it. He nevertheless admitted the possibility of such an active elongation, which he called *ἐκτασις*, in opposition to an active contraction, which he called *συστολή*; (*De Motu Musc. lib. i. c. 9*); and the same supposed active elongation has been put in requisition in modern times, as the proximate cause of muscular motion in general, by D'Hamberger (*El. Physiol. 1751*), Barthez (*Nouv. Mécanique, &c. 1798*), Sprengel

(*Instit. Physiol. 1819*), and many others. This doctrine, however, is, in the case of the sphincters, pretty obviously unfounded; and, perhaps, whenever such an elongation of the muscular fibre appears to take place, as in the instance of the diastole of the heart, which sometimes, as recently removed from a large animal, recoils after contraction with a force sufficient to overcome every resistance which the hands can oppose to it, every thing may be ascribed to the elasticity, partly of the muscular fibres themselves, but chiefly of the cellular tissue which is interwoven with them, and which, by the contractions of the former, had been thrown into a constrained position.

state of the muscle consisted in its elongation, it should, under the general excitement of the voluntary muscles which occurs in tetanus, have yawned like a barn-door, whereas, under the defective stimulation of these muscles, which takes place in palsy, it should have shrivelled up into nothing.

We seem justified in presuming then, that the action of muscular fibre in general, visible or invisible under excitement is to shorten itself; but it does not on this account follow that all motion produced by a physical change in the condition of such fibre, is the effect of its shortening or contracting itself—on the contrary, it appears that, in not a few instances, very remarkable motions result, not indeed from an action, but from a *passive elongation*, or relaxation of the muscles. All the muscles of the living body must be regarded as constantly in a state of some degree of contraction, as might indeed have been *a priori* presumed likely to result from the permanent application of many of the stimuli—that of caloric for example, and the blood circulating in the vessels—to which they are exposed (*a*); so that what is commonly understood by the term muscular contraction, signifies only an increased degree of that state in which living muscles constantly exist. But assuming this as the case, it follows that motion may sometimes result as well from a diminution of this contraction, as from an increase of it; and that if the finger, for example, be held in a state of rest by the equal contractions of its flexor and extensor muscles, it will be bent as certainly by the extensors contracting less than usual, so as to *allow* of this flexion, as by the flexors contracting more, so as to *effect* it. This doctrine, it will be observed, although, like the preceding, it refers the motion produced to an elongation of muscular fibre, still differs essentially from it; since, while in the former the rest was represented as passive, and the motion active, in this, the rest is regarded as active, and the motion passive. And that such diminished contraction of the muscles is really the cause of some motions is sufficiently certain—for example, of the turning upwards and inwards of the eye-ball, of the pinching of the nostrils and of the falling of the jaw under depressing emotions, when the superior oblique muscle of the eye is inadequate to resist the inferior, the levator labii-nasalis to oppose the elasticity of the nasal cartilages, and the masseter and temporal muscles to counteract the weight of the jaw. The closing of the eye-lids and the falling forwards of the head from weariness are equally good examples of motion from diminished contraction of the muscles, the levator palpebræ superioris in the former case, and the muscles on the back of the neck in the latter, being no longer competent to antagonize respectively the orbicularis palpebrarum and the weight of the face. It is from the same cause, also, that the angle of the mouth is drawn towards the sound side, the side of the head pulled down towards the sound shoulder, and the trunk curved in this direction, while the head is rotated towards the affected side in hemiplegia, the paralyzed muscles having lost the power of preventing these several motions; and a similar explanation may be given of the chattering of the teeth from cold, the muscles which naturally keep the jaw steady, deprived thus of a portion of their chief stimuli, acting now only at intervals, and of the shaking of the whole body, either in mental perturbation or in the cold stage of fever, the several muscles acting under these circumstances, not more,

(*a*) This permanent action of the visible muscles, as well as every kind of action of such as are invisible, was referred by Stahl and his immediate followers, as it still is by some authors, to their tonicity, a property which all were supposed to have in common, while the latter, like those of the parenchymatous tissue, were considered, as before observed, to have this property alone, and, therefore, not to be muscles in the strict acceptation of the term. The proposed distinction, however, between tonicity and the proper contractile property of muscles, which is the same as that between the contractility of Blumenbach and Chaussier; and the irritability of the one, and the myotility of the other, seems to be founded principally, as stated by Fordyce (Phil. Trans. 1788), upon the fact that the operation of the former is perpetual, and upon the presumption that it does not require any particular stimulus for its exercise, while that of the latter takes place, it is said, only at intervals, and requires always some particular stimulus to excite it. The distinction, however, appears

to be quite imaginary. At no period during life are the muscles exempt for an instant from the action of stimuli; and the operation of tonicity, permanent as it is, “can signify only,” as observed by Dr. Hastings, “a near state of contraction, and, as such, must necessarily be dependent on irritability”—that is to say, as displayed by muscles, the contractile property characteristic of these organs. It seems, indeed, quite superfluous, as already remarked, to admit of any hybrid property, as it were, between this latter and elasticity, with which indeed the so-called tonicity is very often confounded, as, among many others, by Bostock. “I conceive,” he remarks, “that there is nothing in the phenomena that have been ascribed to tonicity, which may not be referred to the operation of elasticity.” (Syst. of Physiol. 1824, p. 177.) That it is not a distinct property is more than probable; but every view of the matter seems to justify us in identifying it, not with elasticity, but with the proper contractile property of the muscular fibre.

but less than they should do. And it appears to be in this respect that tremors of all kinds differ from convulsions. The motions of the limbs are often in both cases equally powerful; but they take place in the former from an alternating failure of the contractions of certain muscles allied to palsy, in the latter from an alternating excess of such contractions, allied to spasm, the uniform and mutually neutralizing action of antagonizing muscles, which is essential at all times to keep the parts at rest, being equally perturbed in both. Nor is it only the obvious motions which may thus result from a diminished action of muscles, since many molecular motions also, such as those which give rise to blushing, the increased brilliancy of the eye, the turgescence of erectile organs, and every kind of increased secretion, are dependent on the same cause. Hence it has been presumed by some physiologists that, while the action of muscles really does consist in contraction, muscular motion in general depends upon a diminution of this contraction—in other words, upon a loss of balance produced by the relaxation of certain muscles the continued contraction of which was requisite to continued rest. But that this is not the case is obvious from the fact that a stimulus applied directly to a flexor muscle produces flexion; and in doing this it must be supposed to have produced excitement in this muscle, not have withdrawn it from its antagonist—to have acted positively on the organ to which it was applied, not negatively on an organ with which it did not come into contact. Not only, then, is the only action of muscles that by which they shorten themselves, but by far the greater number of the motions to which they give rise results from an increase in the action of those which move, and not from a diminution in the action of those which prevent motion.

The only obvious change which a muscle undergoes under stimulation is a diminution of its length with an increase of its thickness; and the two appear to be so precisely proportioned to each other, that its whole bulk remains quite unaltered. This is easily ascertained by placing a muscle, while still possessed of its contractile property, under water, contained in a vessel the neck of which is drawn out into a capillary tube, when the height of the water in the tube will be found to be exactly the same whether the muscle be undergoing the most violent contractions, or be completely at rest (*a*). The only question, therefore, is how is this change of figure in the muscle—for this is the only change which it appears to undergo during the contraction—immediately effected? The principal hypotheses which have been at different times invented to explain this appear to be resolvable into six, two of which hinge upon the presumption of some influx into the muscle, two upon that of some chemical change, and two upon that of some mechanical change: the alleged influxes are those either of the supposed nervous energy or of the blood, the alleged chemical changes relate either to certain gases which the muscle is presumed to contain, or to its fibrin, the alleged mechanical changes appertain either to the globules of which its ultimate fibres are said to consist, or to its fibres, large and small, themselves. A few words—and a very few will suffice—must be said of each of these hypotheses individually.

(*a*) Experiments of this kind have been conducted principally by Glisson, Swammerdam, and Goddard, who represent the water as sinking during the contraction of the muscles, appearing to indicate that muscles lose in bulk, or, what amounts to the same thing, gain in density by this process; by Borelli, D'Hamberger, Prochaska, and Carlisle, who describe it as rising, seeming to show that their bulk becomes increased or their density diminished under contraction; and, lastly, by Soemmering, Barzelotti, Blane, Sprengel, Meckel, Dumas and Prevost, Mayo, and others, who assert that it remains quite stationary, appearing to demonstrate that their bulk and density remain, as above assumed, unchanged. A great deal of the discrepancy in the results of these experiments may have arisen from the very unsatisfactory manner in which they have been often conducted; sometimes, for example, by thrusting the arm, as was done by Carlisle, into a bucket of water—in which case of course no allowance could be made for the different

quantities of blood which the limb might, under the different conditions of the rest and action of its muscles, contain; at other times, by placing under water a whole living animal—as was Blane's plan—in which case of course no allowance could be made for any opposite change which one set of muscles might be presumed to undergo during the contraction of their antagonists; nor was this source of fallacy obviated by employing, as Mayo did, the heart of an animal for this purpose, the heart consisting of two quite distinct muscles, the action of which is alternate. Allowing for all this, it is only surprising the experimenters should have come so near one another in their results as they have done; and it may be fairly presumed that, had every source of ambiguity been avoided, the uniform result would have been the mean of the opposite conclusions, at which indeed, as it is, so many have contrived to arrive. Magendie remarks, "*La question ne nous paraît pas résolue, mais hereusement elle est peu importante.*"

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

By DR. RYAN.

Dispensary, Gerrard Street, Soho:
Session 1834-35.*

LECTURE XLVIII.

*Entozoa — Invermination — Generation of
Worms—produced by Secretion—Worms do
not perforate the Intestines or other organs—
Classification of Intestinal Worms—Leeches
and Beetles in the human Stomach.*

GENTLEMEN—I have now to resume the history of vermination, as it regards man, and then to describe the pathological conditions caused by the different species of intestinal and some other worms.

Notwithstanding the numerous authorities already quoted in favour of the conclusion that the ova of worms are taken into the body with food and drink, there are many other facts which tend to disprove this view of the question. It is urged, on the contrary, that the worms found in man and animals have a peculiar organization totally different from that of those which inhabit the external world. Again, worms in certain animals present different peculiarities from those of the same species in others, though this is by no means invariably the case. Thus the bothriocephalus and tænia solium in man differ from those of other animals; but the lumbricus and ascarides found in man are exactly similar to those in numerous carnivorous and graminivorous animals.

According to the learned Dr. Fletcher, there are twelve proper entozoa in man; one in the lungs, six in the intestinal canal and its appendages, one in the urinary organs, one in the ovaries, one in the integuments, one in the eye, the brain, and muscles, and one in any organ except the intestinal canal, all quite distinct from numerous other animals, which are reported to have been passed from the stomach, urinary bladder, uterus, skin, and other organs, and the source of all of which was, in all probability, received ova. Every invertebrate animal, and even organ, seems to be distinguished in like manner by its own proper parasite.—(See my Journal, No. 162, 1835, vol. vii, p. 171).

It is also a remarkable fact, that worms are found embedded in the liver, brain, lungs, &c., without any trace of a traject between their situation and the intestinal canal.

Pathologists have also observed that different kinds of these animals inhabit differ-

ent parts of the intestinal canal as well as different parts of the body. Thus we find in man, that the lumbricus inhabits the small intestines and stomach, the tricocephalus the cæcum, and the ascaris the rectum. In fine, intestinal worms have been found in the fœtus in utero of man and animals. From all these facts it is concluded, by some physiologists, that worms are generated within the body, and are formed by the living principle, which renders effused lymph an organized part. "Every new animal, and every new part of every animal is," says Dr. Fletcher, "laid down as a kind of organized germ formed by secretion, and that the axiom omnia ex ovo" in this extended sense, is still unimpeached and unimpeachable. (*Op. cit.*)

This conclusion is however purely hypothetical, and wants further proof to establish it.

It is a common supposition of dyspeptics and hypochondriacs, that the sense of gnawing at the pit of the stomach, from which they suffer, is caused by worms. This is seldom, if ever, true, as the sensation depends upon irritation of some part of the gastric mucous membrane. It is, however, a fact, that round worms are sometimes vomited by nervous, hysterical, and hypochondriacal persons, but this is no more than a coincidence; as in a vast number of such cases which we daily observe in hospital and dispensary practice, no worms are expelled, and proper remedies effect a cure.

Moreover, all naturalists and helminthologists agree that worms cannot gnaw or perforate the bowels; and those examples of perforations which have been observed were the result of irritation, inflammation, and ulceration. Such is the opinion of Rudolphi, Andral, Carswell, and many others, and I entirely assent to its correctness. It satisfactorily accounts for the apparent perforations observed by pathologists. Thus Fischer, of Vienna, relates the case of a woman who had two circular openings in the colon, in one of which was found a round worm, partly in the bowel, and partly in the cavity of the peritoneum. He found a similar worm in the cavity last mentioned, but no more than these two in the whole intestines. It would appear, at a first view, that the worms had perforated the intestine in this case; but many instances are on record, of tumours and abscesses in the regions of the liver, umbilicus, and groins, through which the middle parts of worms presented in the form of a loop, while the ends were embedded in the subjacent parts. In such cases, irritation followed by inflammation and ulceration, could alone account for the perforations.

I have already stated that worms have been found in solid organs without any vestige of a traject; thus they have been discovered in the substance of the liver, brain, lung, heart, ovary, uterus, &c. &c. It is also

known that different species infest different organs and portions of the digestive tube.

Some are found in every part of the intestines, others in certain parts only, and some in different organs.

I shall, at present, confined myself to the description of intestinal worms, and adopt the classification of Dr. Mason Good, which is as follows:—

Helminthia alvini—alvine worms.

----- *podicis*—anal worms.

----- *erratica*—erratic worms.

Alvine worms are divided into the following varieties:—

1. *Ascaris lumbricoides*—long round worm.

2. *Tricocephalus*—thread-worm.

3. *Tænia solium*—tape-worm.

4. ----- *vulgaris*—broad tape-worm.

5. *Fasciola*—flake-worm.

The commonest human worms are—1, the lumbricus, or round worm; 2, *tænia*, tape-worm, with its two varieties; 3, *tricocephalus*, which inhabits the cæcum; 4, *oxyuris vermicularis*, or the thread-worm of the rectum.

1. *Ascaris lumbricoides*, or round worm, is often from twelve to fifteen inches long, though, in general, it is much shorter; it is transparent, or of a greenish yellow or straw colour, as you perceive by the specimens now presented to your notice. It usually inhabits the small intestines, and sometimes the stomach of thin persons; it frequently ascends into the œsophagus, and creeps out at the mouth or nostrils, and sometimes, having arrived in the throat, turns into the glottis or commencement of the windpipe, and causes suffocation. A most remarkable example of death caused in the manner just mentioned, is related by M. Andral. It occurred in a child apparently in health, who was suddenly seized with difficulty of respiration, which caused suffocation and death. On examining the body it was found that a large lumbricus had ascended from the stomach and arrived at the glottis, into which it turned, excited difficult respiration, suffocation, and death.

This species bears a striking resemblance to the common earth worm, and many naturalists have pronounced both the same. It often remains quiet, and is only discovered by its discharge; but, in general, it is troublesome, producing an intolerable feeling of sinking at the epigastrium or pit of the stomach, much emaciation, pale countenance, foetid breath, and itching of the nostrils and anus. Many of you, no doubt, recollect the female patient at the hospital, who suffered from all these symptoms, and expelled, by vomiting, a round worm six inches in length. I knew a young lady from whose mouth and nostrils this worm frequently crawled, to the terror of her schoolfellows.

2. *Tricocephalus*, or long thread-worm, is found in the cæcum of sickly delicate children. It is also detected in the horse, boar,

fox, and mouse. It is about two inches long. A vast number of this species is said to be expelled by the negroes in the West Indies.

3. *Tænia*, or tape-worm, is generally found in the small intestines, and also in the stomach, colon, and rectum. It consists in numerous joints, and measures from 10 to 114 feet in length. Bresmer relates a case in which it measured 150 feet long, and it is even said to have doubled this extent. It is stated, in the Medical Transactions of Copenhagen, that a tape-worm measured 800 ells in length. It generally inhabits the duodenum, jejunum, and ileum, and is said to feed on the chyle. It is supposed to reproduce parts which may have been broken off; and it is sometimes expelled like gourd seeds, and hence called gourd-worms. Its structure is very imperfect, and inferior to that of other intestinal worms. It is said to want a nervous and sexual system. There are no symptoms by which we can distinguish the presence of this, or, indeed, of any other species of worms, unless when we see them after expulsion. A curious exemplification of this fact lately fell under my observation at the hospital. A pensioner, who had served under Sir John Moore, at Corunna, supposed he had worms. His complaint appeared to be dyspepsia. Among other things I ordered castor oil and oil of turpentine, as a purgative. He passed a flat tape-worm which measured nine feet, and which I now show you. He told the result to many of the out-patients who suspected they suffered from worms, and earnestly requested the medicine above mentioned. I gratified a few of them, but no tape-worms were expelled.

4. *Fasciola*, or fluke-worm, is rarely found in man. There are apparently many different species of ascarides, or anal worms. All are generally situated in the rectum, exciting troublesome local irritation, which extends along the whole intestinal tube to the lips and nostrils, causing itching of these parts, which induces children to pick and excoriate them. In other cases, the worms crawl from the bowels, and irritate the adjacent parts. In some cases the child grinds the teeth when asleep, starts affrighted from sleep, and fancies the presence of frightful objects. The breath is also foetid, or offensive. The irritation in the lower bowel is communicated to the genital organs, as both organs are supplied by the same nerves, and strongly sympathise with each other; and thence we often observe purulent or yellow discharges from the genitals of both sexes. All these symptoms may, however, exist, independently of worms, and there are none that can be relied on.

The species of ascarides are the following:—

1. *Ascaris vermicularis*—thread-worm.

2. ----- *scarabeus*—beetle-grubs.

3. *Ascaris æstrus*—bots.

The first are also called maw-worms, from having been frequently discovered in the stomach or maw. The second may exist in the stomach and intestines, as I shall immediately prove to you. The third, including the breeze or gad-fly, have been found in the fæces of man and animals. It is said that their ova, or eggs, are deposited in the nostrils of sheep, are hatched, and travel to the frontal sinus and horns, giving rise to vertigo, great irritation, which leads the animals to shake their heads violently, and to rub their noses in the gravel or dust. These worms may finally pass by the nostrils, or cause inflammation of the brain. The eggs are said to be deposited on the lips of horses, to be licked off, swallowed, and finally to reach the rectum. They have also been found in the lower bowels of grooms and horse-dealers.

The last class of worms called erratic, as the gordius or hair-worm, the *hirudo* or leech, and the *musca* or maggot, have been introduced into the bowels, examples of which I shall cite.

The hair-worm is common in the rivers in Lapland, and is sometimes seen in those of these countries. They are swallowed by peasants, who drink from marshy, stagnant pools, and cause violent gripings and discharge of blood from the bladder. After a few hours or days, salivation comes on, which does not continue longer than half an hour, when all unpleasant symptoms cease.

Hirudo. Leeches have been swallowed by men and animals. One of the earliest accounts is that of Pliny, who states, that elephants, which swallowed leeches, were cruelly tormented by these animals in their stomachs. Numerous examples of leeches expelled from the human stomach might be cited, but the following will suffice:—

Mr. Paisley described a case in which a patient discharged two worms, like the common horse-leech, each one and a half foot in length, and one and a half inch in diameter, dead, and filled with blood, and accompanied by a discharge of several pints of blood. (Ed. Med. Essays, v. ii). Dr. Bond, of Philadelphia, describes a case in which a worm got through the hepatic duct, made great devastation there, travelled back again, and was finally expelled. He calls it the hepatic leech. (Lond. Obs. and Inq., vol. vi.) Baron Larrey, “the honest man, and best surgeon, Napoleon ever knew,” has given us a most extraordinary account of the depredations of leeches in the human fauces and stomach, and which I translate from his *Memoires de Chirurgie Militaire*, t. i, p. 359. “During the operations of the French army in Egypt, pools of soft, muddy water were frequently met with, particularly in the deserts bordering on Syria. These contained, among other animals, a species of leech, as fine as a horse hair, but which

acquired, when gorged with blood, the volume of an ordinary leech. The soldiers, urged by thirst, and unsuspecting of danger, threw themselves down on the margins of these lakes, and drank with avidity; but many soon experienced the baneful effects of the leeches which they had swallowed. Painful stinging in the posterior fauces, frequent cough, and expectoration of glairy mucus streaked with blood, and a disposition to vomit, were the primary consequences of the bite. To these symptoms succeeded swelling of the throat, frequent hemorrhages, difficulty of swallowing and respiration, pains in the breast, cough, from irritation of the animal's tail near the glottis, and, perhaps, by the effused blood upon the part, perceptible emaciation, loss of sleep and appetite, restlessness, agitation, and death.”

In the first individual who was examined, a leech, as thick as the little finger, was found attached to the fauces, and was with difficulty extracted with a polypous forceps. Slight hæmorrhage succeeded, and the patient recovered. In other instances, gargles of vinegar and salt water, injections of salt water, fumigations of tobacco and squill, were successfully employed to dislodge the leech from the posterior fauces. Sometimes the animal descended into the œsophagus and stomach, and, after remaining for some time, was at last detached by the use of diluted vinegar, and by the contraction of the organ, and, perhaps, by the gastric fluid. Another man was harassed nearly to death before the cause was discovered; and at length a leech was extracted as before, and another passed from the nose. Baron L. thought another man laboured under nasal polypus; but, on touching the substance, he saw it contract, and, on pulling it away, found it to be a leech of an immense size. It has long been advised, that water ought to be filtered or boiled before use, especially if taken from a stagnant pool. The ancients were aware of this fact, and hence you will find Pliny has described the pain caused to elephants that swallowed leeches when drinking; (l.viii):—“*Cruceatum in potu maximum sentiunt hausta hirudine, quam sanguisugam vulgo cæpisse apellari adverto.*” The old writers recommend salt, vinegar, garlic, assafœtida, mustard, and other acrid substances to be copiously given, with sternutatories of hellebore and elaterium; and when pain was violent in the throat, to hold cold water in the fauces, in order to decoy the leech from its situation. In the *Ephemerides des Curieux*, 1719, a case is related, and styled *Cardialgia Hirudinosa*; the patient, after an emetic, brought up five leeches, four small and one the size of his finger; they were all gorged with blood. He speedily recovered. Dr. Davy has given an interesting account of the leech of Ceylon, which possesses an acute smell; for, no sooner does a person

stop where such abound, than they crowd eagerly to the spot from all directions.

In rainy weather, it is shocking to see the legs of men on a long march, thickly covered with these creatures gorged with blood, which is also trickling down in numerous streams. It is impossible to ward off their attacks. Their bites are painful, and are apt to run into ulcers, sometimes occasioning the loss of limb and life. In many British medical works we find cases recorded, in which small worms came from the nose, malar bones, frontalsinus, and appeared on the surface of ulcers in various parts. M. Itard relates a case of violent otitis which withstood all treatment; at length almond oil was poured into the ear, when the pain ceased, and on removing the oil a worm came forth. In fœtid discharge from the ear, insects often deposit their ova on the part, and thus we can account for the occurrence of M. Itard's case. I know a patient who, during menstruation, passes small worms like ascarides from the uterus: perhaps these are hydatids. I mention the case in my work on Obstetrics: the woman is still alive. But to return to Dr. Good's species. The third variety is *musca* or fly. These deposit their eggs in game and other meats, that have been long kept and are approaching a putrid state, as the *M. carnaria*, flesh-fly, *M. vomitoria* or blow-fly, *M. abaria* or pantry-fly, *M. putris*, called hoppers by housewives, or maggots. These perforate and lay their eggs in cheese, bacon, hams, and other salted provisions.

From the deposit of the eggs of these species of fly in so many articles of the common food of man, there is no difficulty in conceiving how they pass into the human intestines. They cannot live in a healthy stomach, but in a debilitated one they find a comfortable nidus through the entire range of the intestinal canal. Thus, Dr. White had a patient labouring under all the symptoms of dyspepsia. The usual remedies were useless, at length purgatives were used, when numbers of pupæ or chrysalid worms were expelled, and on being preserved they became the *M. cibaria* (Mem. Med. Soc. Lond.) The caddy insect has passed in the same way (Op. Cit., and another case (Ed. Med. Com.), various other fly maggots (Cent. Obs. 85), the larvæ of the bee (Obs. Med. iii, Cur. Wolffén, 1723), and even living spiders (Jour. du Med. iv); lizards, the *lacerta aquatica* (Jour. du Medicine, T); Wolffén also. A snail was found in the stomach (Hufeland's Jour. 1829). All these animals are so changed from a residence in the human body, that it is a matter of difficulty to determine, in many cases, the exact external species to which a larva, worm, or animalcule, within the body may belong. Thus, in one case, the horse-leech has been the size of a man's fist, and contained a pint and a half of blood.

A most remarkable example of the introduction of the ova of insects into the sto-

mach is described by a recent writer, whom I shall quote.

Dr. Pickells, of Cork, relates a most extraordinary case of a young woman, aged twenty-eight years, of a melancholic temperament, possessing a high degree of nervous sensibility, and a religious frame of mind, who discharged a vast number of the larvæ and pupæ of the beetle, as well as perfect insects, from the stomach. The history of the case will be found in the Transactions of the Association of Fellows and Licentiates of the King's and Queen's College of Physicians, v. 4, 1824, from which I condense the particulars.

The subject of this singular case was affected with vomiting of blood, occasional convulsions and catalepsy, and dropsical swellings. The catalepsy continued for a few minutes in general, but sometimes for hours. She had also amaurosis and curious optical illusions. She ate freely of chalk, to mitigate heart-burn. Her appetite was bad, the mouth parched, thirst and confined bowels. A variety of remedies were employed for her relief, but without success. She was so bad that, during a period of three years, the rites of her church were administered no less than fourteen or fifteen times.

After the use of brisk purgatives, she vomited the larvæ of a species of beetle, accompanied by hæmatemesis and convulsions. She described one of them, "a green thing, as long and as thick as one of her fingers, which flew. It had wings, a great many feet, and a turned-up tail. She saw it distinctly leap, and clap its wings. She took it in her hand, and put it into a wine-glass, which it almost filled, and which she covered with paper to prevent its escape. It forced its way out of the glass, flew on the table, and then on the floor. She was now seized with convulsions, and upon her recovery, neither she nor her aunt could find it in the room." She offered to make oath to the truth of the statement.

Emetics were given her, when she vomited a great number of "winged ones." These were seen by Drs. Pickells and Herrick, of Cork. She also passed several by the bowels.

She brought nine or ten large ones, which irritated the œsophagus and caused hoarseness for a week after the expulsion of each.

The fits were supposed to be epileptic, but I should rather think were hysterical, from the manner in which they were arrested*.

Her bowels were costive, and the dejections, when not bloody or purulent, were dark and sometimes green. The catamania were suppressed. The pulse was from 80 to 90. Her mental faculties in the intervals

* *Digitò medici in vaginam intromisso et in os uteri adpresso, semper cessarunt convulsiones, eo annoto autem, redierunt. Hoc experimentum sæpius iteratum fuit à Doct. Keogh, Casey, et Bull.*

of attack were clear and unclouded, but she often traversed her apartments with a wild and hurried step, occasionally uttering the loudest and most bitter shrieks, tearing her hair, or attempting to strike her head against the wall, and calling in a loud voice for her mother, who had been eight years dead.

Dr. Pickells avers that she vomited seven hundred of the larvæ of the beetle, and passed a hundred by the bowels. According to the patient's account she vomited myriads of the larvæ of the dipterous insect, and these were alive and moving. The number of winged ones was about sixty.

"The larvæ of the beetle," says Dr. Pickells, "were, with few exceptions, lively and vigorous in the extreme, nor was it possible, without a feeling of horror, to view them frisking along the bottom of the vessel in which they were preserved, occasionally expanding their jaws, and extending their denticulated feet or talons, as their unfortunate victim used to call them. Some were apparently dead, but revived on exposure to heat." She also discharged some of the larvæ of the musca or fly. In fine, she discharged the larvæ, pupæ, and imago of the same insect, which proves that the successive metamorphoses of insects may take place in the human stomach and bowels during life. These metamorphoses are illustrated in the work from which I have quoted, and I now submit them to your inspection.

The mode of introduction of these insects was so singular, that I quote it verbatim.

"In an anxiety to elicit every circumstance which might tend, in the slightest degree, to develop the mode of introduction of the insects, I once asked her, whether, independently of the chalk, she had ever been in the habit of eating clay. Her answer to this question unfolds a tale which I regret to have to record, as a degrading instance of superstition. When she was about fifteen years of age, it appears that two much-respected and popular clergymen of her persuasion having died, she was told by some old women, that if she would drink daily, during a certain period of time, a portion of water imbued with clay taken from the graves of these clergymen, she would be secured for ever against both disease and sin. She accordingly walked to Kinsale, a distance of twelve miles, where one of the clergymen was interred, and succeeded in bringing away an apron and pocket-handkerchief full of clay from his grave. To this she added, upon her return, a handkerchief and some mugs-full of clay, obtained from the grave of the other clergyman, who was buried in this city. Her practice was, to infuse water from time to time, according to the exigency, in a vessel containing a proportion of clay so collected, the mixture having been always allowed to rest until the grosser particles of clay fell to the bottom.

"She had been for some time engaged in

a daily use of the water, medicated according to this disgusting formula, when the clergyman of her persuasion under whose direction she was more immediately placed, having discovered the unnatural practice, came to her, and rebuked in the severest terms her infatuation; and, not confining himself to the mere remonstrance of words, went so far, in the effervescence of a just indignation, as to break in pieces one of the vessels which contained the clay, being the only one that came under his observation. Notwithstanding this severe and merited rebuke, she still persisted in the use of the clay, until the whole quantity was gradually consumed.

"The blaps mortisaga, it is well known, inhabits such situations as church-yards. This occurrence, however, happened about twelve years prior to the first discharge of insects; and it seems difficult to reconcile with analogy the supposition of their having so long remained in the system. It may also be stated that she has known several other persons, including among the number adults, who used the clay in the same manner, and at the same time, as herself, but that she never heard of their having subsequently experienced any peculiar ill effects."

It is a curious coincidence, that there is another case very similar to the preceding published by Dr. Milner Barry, of Cork, in the Dublin Medical Trans. v. 2, in which a whole family, who went to reside in the vicinity of Cork, became affected with worms. One of the servants observed exactly, what she termed the same kind of worms as those passed by the family, in a well, from which she took the water for their use. Dr. Barry was also of the same opinion. He advised the discontinuance of the water, and he soon cured the family of the worms.

By JAMES MANBY GULLY, M.D.

LECTURE XIII.

Bucco-pharyngeal Inflammations. (Continued).

THE treatment of amygdalitis comprehend three principal indications, 1. to relieve the engorgement, 2. to cause revulsion, 3. to supply air when the disgorgement and revulsion are insufficient. If the phlegmasia is purely inflammatory and tends to suppuration, it may on the onset be stayed by local bleedings, by leeches to the throat: in this disease it is that they were first employed. By them you are enabled to obtain a speedy relief, because an external tumefaction and capillary injection exist in the

cervical subcutaneous tissue and ganglions, which favour their operation so as frequently to annihilate the disease at once, always provided it be taken early: for should it have existed two or three days, and resisted leeches, we may expect suppuration, and we are then confined to the use of emollients and revulsives: the suppuration takes place in one tonsil and the fever abates. Individuals differ widely as regards the termination of tonsillitis; in some it always ends by suppuration, and in others in resolution: this depends on individual peculiarities. I have known persons that have had five or six attacks of quinsey in the space of as many years, and in them it has always ended in suppuration.

Another chance is, that as the swelling and dyspnœa augment, suffocation is imminent. The treatment must then be changed immediately that we see no sufficient effects from general or local bleedings: the tonsil must be incised or tracheotomy performed to save the patient. Asphyxia however, scarcely ever happens, but in those whose tonsils are swelled anteriorly, and in whom the inflammation is most intense; I saw one case of death from the disease in the hospital of Udino in Italy: the tonsil, enormously enlarged, filled the entire of the pharynx and kept the epiglottis firmly pressed down.

The first and third indications are fulfilled by the above means: but an intermediate one is revulsion, effected either on the extremities by means of irritating pediluvia, or on the digestive canal by purgatives, provided the patient is robust, and his secretory organs readily respond to stimulation from natural tendency or from habit; for we may accustom ourselves to artificial humoral evacuations until they become almost as easy to produce as are the natural.

When the inflammation extends to the viscera it must be arrested there: this necessity is palpable.

After this acute stage a chronic swelling sometimes remains in the tonsil and is continually troublesome to the patient: for this scarification has been advised, and I have practised it several times with, however, but small success. I have done better with one or two leeches applied to the tonsil by a tube, as you may remember to have seen latterly at Val de Grâce. Recourse may also be had to a counter-stimulant indication, all kinds of astringent gargles combined, in the case of great tenderness, with opium and the acetate of morphia. You should try all these means, since they are adapted to cause a contraction of the tissue of the organs and to effect resolution: should they fail you have ablation or cauterization as a last resource. Previous however to putting them into practice, you should essay and insist upon a mild vegetable and milk diet, entire abstinence from wine and fermented liquors, and have recourse to gentle laxatives or purgatives provided there is no contra-indication.

Such means I have certainly seen to succeed in individuals whose tonsils remained enlarged and indurated after repeated inflammatory attacks connected with an exaltation of sensibility in the nervous papillæ of the velum palati. Revulsives, such as blisters, are not contra-indicated, but they are less beneficial in this than in other circumstances. It is almost superfluous to mention that in the event of the suppression of an hemorrhage, of any external suppuration, of a dartre, hemorrhoids, habitual sweat, &c., the discharge or irritation should be recalled to its primary seat.

Pass we now to the same inflammation with mucous secretion or to the exudatory form. Here the follicles are more particularly the limit of irritation and the centre of fluxion: the sanguineous capillary network of the gland and its proper substance take little part in it. The causes of this inflammation are cold, particularly cold and moisture—and a peculiar predisposition: miasms contained in moist and cold air have little to do with it. In the commencement it is only a slight sore throat; on looking into the back of the throat we perceive a *couenne* or false membrane applied on the tonsil and more or less fetidness; this shade is referable to the diphtheritis of M. Bretonneau. I have already told you that all the shades of inflammation are possible in epidemics, and that it may attack the same organ sometimes in one, sometimes in another point, but that it never has a uniform and identical form. When people describe epidemics to you as having this identical form, be assured they are romancing; you should take each individually for what it really is, and not lose yourselves in the sloughs of abstraction and ontology. Now, in diphtheritic epidemics, you see individuals who have diseased tonsils without having two or three days of antecedent fever, and others again, who, on the contrary, have had a previous gastritis or pneumonia. If you mix up these facts you fall into confusion: and this is just what has been done in the histories of the epidemics now under consideration. These histories contain cases wherein the affection was confined to the tonsils—these they cure: and others in which it had been preceded by internal diseases—these they failed to cure. On these facts I lay violent hands, and I say if you see a fibrinous sore throat without fever or any sign of internal phlegmasia, it must be admitted that nothing but the sore throat exists; but the patient has suffered from the action of a powerful modifier that has deranged his mucous secretions and unfavourably predisposed the system; this modifier is simply moist cold and it is in vain to bother your head with seeking for another cause; as it has been acting for a long time its effects cannot be confined to a small point and extend to several organs at once. Two things therefore are possible—local and

isolated phlegmasia of the tonsils without fever, and multiplied phlegmasia with fever. As to the tumefaction of the cervical ganglions it does not apply exclusively to this shade; we see it in all inflammations of the throat according to the individual constitution. In it the lymphatics are more especially exposed: the same may be said of it as of mesenteric engorgement with reference to gastro-enteritis—young and lymphatic subjects most frequently suffer from it.

What becomes of this kind of amygdalitis? If it be not arrested, and there be an inflammatory predisposition in the viscera, it extends thither; if only half combatted it remains more or less circumscribed in some point, though it has no invariable progress. In this case, as the inflammation is not urged on with the same violence as in the preceding kind, it does not tend to phlegmon; it is a simple mucous irritation resident in the follicles.

The prognosis is taken from the intensity of the inflammation, and from the exudation: the thicker and more adherent this is the more danger is there, and *vice versa*, though, when thin, it certainly has a greater tendency to propagation. While local it cannot be fatal; but should it be communicated to the larynx, the same secretion that is innocuous on the tonsils is not so in that organ, and croup and its consequences may ensue.

Your duty, as physicians, is first of all to combat the inflammation. If it is sufficiently pronounced to authorize recourse to sanguineous emissions, hesitate not to practise them. When there is external heat or engorgement leeches are excellent; if after applying them the morbid secretion continues, I do not forbid you to strive to alter it. From the onset, you are aware that I have laid down three principles in the treatment of phlegmasiæ; first, sanguineous emissions; next, local stimulation, or counter-irritation; and thirdly, revulsives and perturbing stimulation. Throughout the whole course of my medical life, I have constantly taught and practised these principles, and I wonder that people are not tired of twaddling about my eternal use of gum water and leeches—ignorance or malignity must surely guide them. I hold all means to be good provided I can adapt them to individual susceptibilities. Thus, when you have destroyed the inflammatory congestion, use, if you think proper, topical remedies that may change the morbid secretion, alum, lunar caustic, or muriatic acid. But rest not your whole hope on these means, because after having momentarily arrested the inflammation, you stand a chance of seeing it reappear and extend to the lungs and stomach; the surest way is to utterly annihilate it. Be not, however, enthusiastic in any one means; all are open to you. I have never systematically and obstinately recommended sanguineous depletions alone; I have only in-

sisted on the necessity of a method or mode of arrangement, by which facts might be generalized so as to apply readily to the treatment; such a method appears to me preferable to the arbitrary creation of specialities, the admission of which requires an effort. What then is meant by those who assert that we order nothing but leeches for every disease? they limit us and our means, and they diminish the honour they would have in vanquishing us—less cunning than Don Quixote, who magnified his enemies in order to acquire the greater glory in overcoming them*.

Pharyngitis.—We now follow inflammation into the pharynx, where it may be either primary or secondary; in the latter case—of which I do not propose to speak at present—the inflammation either rises from the bronchi by the larynx, or from the stomach by the œsophagus; when primary, it arises from all the causes that produce inflammation of the fauces. But, you will ask me, are you sure that it can actually exist primarily and apart from the exudatory form? Yes, and I affirm it, although M. Bretonneau has represented it as always associated with fibrinous inflammation of the velum palati, the tonsils, the pharynx, and the mouth; I assert it, because I have seen it, and having the organ of immediate observation of facts, I forget none that I do see. By this power I have certified all the various commencements of this affection, by the tonsils, the velum, pharynx, bronchi, lungs, &c.; besides, know we not that inflammation may begin at any and all points?

Thus primary, it is exhibited in two forms (as are all mucous phlegmasiæ), one dry, the other humid; the dry form arrests the follicular secretions by the violence of the sanguineous congestion, which is sometimes so intense as to, for a short time, redden and cause the tumefaction of the posterior part of the pharynx. How should we treat such a rapid phlegmasia? imitate, by the promptitude and energy of our antiphlogistic remedies, the promptitude and energy of the inflammation, bleed with the lancet if there be congestion or plethora, apply leeches in great numbers to the throat, use emollient injections, pediluvia and irritating glysters, and, in hot weather, apply ice on the throat, after the leeches. When the congestion is in the portion of the pharynx nearest to the base of the skull, and active measures have

* I recommend the whole of this paragraph to those ingenious critics who pretend to know an author's doctrines better than the author himself, or who—and these are the most numerous—know nothing at all about either author or doctrines, yet denounce or sneer at both. A specimen of the latter tribe is a writer of the article on "French Surgery" in the last number of Dr. Johnson's Journal, whose coarseness is only equalled by his ignorance.—J. M. G.

been used, it yields; in the other case it may go on to suppuration. A simple phlegmasia of the pharynx may become an obstacle to respiration; this necessarily rare case requires tracheotomy.

Humid and fibrinous pharyngitis, which is less intense than the preceding, requires, after antiphlogistic means, detersive stimulation and topical means to alter the secretory inflammation, as also revulsion. If you have stimulated too much, return to leeches and emollients: make no vow to abandon either the antiphlogistic or the stimulant plan; use both alternately, as they are required. Next come the laryngeal inflammations.

Laryngitis is one of the most formidable diseases, on account of the narrowness of the glottis, particularly in infancy, and the disposition, at that age, to mucous secretions that easily coagulate. I am of opinion, that the facility with which false membranes form in the larynx, is owing to the heat of respiration and of inflammation: the respired air absorbs the moisture of the pharynx, larynx, and trachea, and dries the mucosities of those parts.

We have not to treat of inflammations of the internal surface of the larynx alone; as we proceed from the exterior to the interior, it is better first to mention the external inflammations of the organ that have nothing to do with mucous membrane; for such exist, and have been denominated *œdematous laryngitis*, or *angina*, words that are vague, but which will be shortly explained in the sequel.

There are, in the region of the larynx, muscular layers, layers of filamentous, lamellar, and membranous tissues, innumerable vessels and nerves, a cutaneous envelope; and, in the composition of the organ itself, cartilages, ligaments, minute synovial capsules, &c. In all these parts inflammation may appear, and I have, with wonder, seen it take its start from each of them.

I shall class the cellular and capsular inflammation together. They are generated under the influence of all the causes of irritation, and are determined by efforts of the voice, singing, crying, &c. Not unfrequently we see them, in our military hospitals, attack officers, whose place it is to give the word of command at the pitch of their voice, without having any regulation of the voice, as in the church or at the opera. Such a result, from giving the word in battle, I have frequently seen, and have been terrified with the intensity of the disease thus originated. One would think it only acted on the mucous membrane, but it affects the whole larynx, and may produce inflammation in all the tissues I have mentioned. Sometimes blows, falls, or attempts at strangulation cause it: persons whom robbers have endeavoured to strangle, have been known to suffer from it; and, after being apparently cured, have retained

a nucleus of irritation that has eventually disorganized the cartilages of the organ. Rheumatic affections may likewise sometimes attack the small articulations of the larynx; I have seen cases where individuals, after suffering intolerable pains of the extremities, were seized with swelling and inflammation of the larynx, sometimes acute, at others chronic, subsequently to which the usual traces of phlegmasia in the capsules, and surrounding cellular and muscular tissues, were detected. The degree of the inflammation was dependant on the activity of the stimulation, the predisposition of the individual, and the manner in which the disease was managed.

In regard to symptoms, this phlegmasia should be divided into the intensely acute and phlegmonous, and the subacute, tending to chronicity, the latter being most frequently only the consequence of a less degree of stimulation than the former. Ensuing on the above-named causes, particularly cold acting on a plethoric and heated individual, the four phenomena of inflammation are seen to arise about the larynx. The redness is not very intense, there is only somewhat more injection than if the phlegmasia was more internal; the patient feels a burning, tension, and stiffness of the throat; add to which the tumefaction—and this is readily ascertained—and you have all the positive signs of inflammation. Next come the negative signs; and these are, the absence of râle, of cough, hoarseness, or any internal irritation that leads the patient to forcible expectoration: there is no internal stimulation, but pain, heat, and a sensation of depression; absence of pain, in deglutition, has been added to these signs, but this is not always the case, and depends on the individual sensibility. When inflammation exists in an organ, every effort to displace it may induce pain therein, and pain is, therefore, possible in deglutition, in this instance, as well as in mucous laryngitis. Briefly, to establish your diagnosis, you make manual examination, you find swelling, heat, throbbing, nothing within the throat, and you conclude that the phlegmasia is external. It then becomes a matter of small consequence whether the *œdematous swelling*, threatening phlegmon, be the consequence of an irritation of the capsules, or a simple phlegmasia of the cellular tissue; the really essential point is to form ground for your therapeutical acts.

When this phlegmasia is considerable, it may act on the pulse and produce fever: this, however, is not an essential symptom; indeed, it does not necessarily belong to any phlegmasia, but only to certain degrees of it: a tolerably severe external laryngitis may exist without frequency of pulse. The sympathetic phenomena of malaise, lassitude, &c., almost always are present. If not arrested, the disease may go on to sup-

puration: I have seen an abscess of the larynx open, empty itself, and leave the great cartilage bare, yet the patient get round without any serious effects on the viscera. Such terminations are possible when the inflammation is purely cellular; but when the nucleus of it is placed in the centre of one of the laryngeal articulations, this nucleus continues notwithstanding the suppuration it produced, and there then remains pain, sensibility of the part to the touch, the minute phlegmasia gains in intensity, and may end in caries of the cartilages, and laryngeal phthisis. Sometimes an induration of the surrounding cellular tissue takes place, a semi-scrofulous condition; a consumption may even come on, and one is puzzled to determine the exact cause of these disorders. What you must do is, ascertain whether the phlegmasia is internal or external, see whence it can originate, whether it is connected with some rheumatic affection, and which is the most sensitive point of the larynx, in order to direct your remedies thitherward. So long as the disease is purely external, no one dies by it: suppuration takes place, and is followed by cicatrization. Cellular phlegmasiæ only prove fatal when they occur between large muscular masses, and produce immense purulent discharges, sloughs, &c.; but in this case it may chance not to be simply cellular, and after the evacuation of the pus, may remain fixed in some articulation of the laryngeal cartilages; it then becomes a chronic disease, which gradually disorganizes the parts, and is ultimately incurable. The patient dead, we find an inflammatory condition of the larynx, and other inflammations that have extended their ravages into the visceral apparatus, and even to the lungs; astonished at the extensive mischief, we look for the starting point and find it, like a minute thorn, in some of the small laryngeal articulations—a diminutive cause of such prodigious effects.

The prognosis is simple; when intense and cellular, there is nothing to fear from the inflammation; but when it is obstinate after passing the acute stage, when there is fixed pain in the larynx increased on pressure, it is very probable that caries is forming; so long as this is limited, there is no danger: but when the irritation that produced it is repeated in the viscera, and causes bronchitis, pneumonia, tubercles, &c., we can have but slight reliance on curative means.

The treatment should be antiphlogistic in the onset of the disease. Again I tell and shall continue to tell you, almost all phlegmasiæ may be arrested if taken in time and vigorously attacked, unshackled by vain fears of debility and of adynamia. After combatting the acute stage, if there remains a painful point, without fever, and there is reason to suspect an affection of the cartilages, antiphlogistics are no longer sufficient; we must bring in aid local suppuration by

moxas, and at the same time apply emollient and anodyne remedies to the wounds, enjoin complete silence and quietude, avoid whatever can put the diseased parts in commotion, and prescribe milk diet; in this manner you will succeed, provided you have not to deal with a patient of bad constitution. Relapses very easily occur, particularly when there is caries of the cartilages, which when once they are disorganized, never again regain their correct positions, and are thus an incessant obstacle to a cure. Such is the disease that has been denominated œdematous angina, a disease that may exhibit varied degrees of intensity, and which is naturally allied to the preceding ones, especially to the articular inflammation. It has been supposed to be accompanied with an infiltration of the internal parts of the larynx, but this is mere imagination.

We now come to croup, properly so called, or to the inflammation of the laryngeal mucous membrane. It has been seen in a variety of forms, all, however, reducible to two, one purely inflammatory without false membranes, the other much more common, less inflammatory, and with secretion of false membranes. It is important to make this distinction in considering the disease both in the adult and the infant. We certainly remark in the former violently inflammatory mucous phlegmasiæ of the larynx without supersecretion, and widely different from those of the latter. In my military practice I have frequently seen persons attacked with violent pains in the regions of the larynx, without external tumefaction, without sensibility on pressure, without, in short, the symptoms of the preceding phlegmasia or œdematous angina. These persons were adults of a sanguineous constitution, had given way to excesses in stimulants and spirits, or had been making violent vocal efforts. They breathed with difficulty, had pains of the larynx, frequently applied their hands to that organ, threw the head backwards, and contracted the elevator muscles of the chest with difficulty; when the disease had reached a high degree the eye became restless, the countenance uneasy, with an expression of intense anguish. Some of them exhibited signs of hydrophobia, convulsive movement at the sight of water, symptoms which I may state in passing may also be observed in tonsillary angina. These individuals neither presented any mucous excretion nor râle that could announce the formation of mucosities in the larynx; on the contrary, that organ was dry and burning. Such were the positive and negative symptoms of this shade of croup. The same shade has been observed in children, but rarely, because croup being a disease of localities, and cold and humid seasons, it is necessarily accompanied with mucous secretions. In reading the numerous works that were published for the

prize instituted by Napoleon, we may observe that the shade in question is much more frequent in adults than children.

This phlegmasia has been ascertained by the inspection of individuals cut off by strangulation or pulmonary congestion; the mucous membrane was red and swelled, nearly or completely obliterating the respiratory passage. Death, however, was attributed to spasm: now, you are aware that wherever there is a phlegmasia the neighbouring muscles contract irregularly, and are seized with spasm; but do not believe that spasm is the fundamental character of the complaint. These spasms are always in ratio of the obstacle to respiration, and the more or less nervous constitution of the patients. They may undoubtedly aid in the suffocation; but the obstacle to respiration from the tumefaction of the mucous membrane, and diminution of air-passage, are sufficient to account for it; besides which pulmonary or encephalic congestion may be the immediate cause of death. Dissections, related by many authors, will suffice to shew you how possible suffocation is in these kinds of phlegmasiæ.

Would you form an idea of their danger, observe whether the head is injected, whether the respiration is incomplete, the skin livid, whether the patient becomes livid: if so there is danger. But, so long as there is only pain, agitation, impatience, hydrophobic, and nervous symptoms, there is nothing to fear: all this is made to disappear by general bleedings, if the head and lungs are congested; by leeches to the larynx, if it alone is implicated, and these means are seconded by pediluvia and sinapisms. Any consecutive phlegmasia of the head or lungs must be treated in like manner.

The laryngeal phlegmasia, of which we now speak, may be connected with that mentioned in the preceding part of this lecture—may be either its cause or effect, or may be so complicated with it as that the inflammation, after being external, becomes internal, and *vice versa*, or it may be both at once. However, there is no specific treatment for this case, no antispasmodics, nor narcotics, such as musk, camphor, belladonna, &c.; it is still a phlegmasia to be combated by antiphlogistics, and then lulled by anodynes, in susceptible persons.

There is a disease that has been likened to this laryngitis, and has received the name of the "asthma of Millar." Much has been said of it, and there are doubts whether it should be constituted a specific order; for my part I believe it to be distinguished by a pulmonary congestion, depending on some disorder of the circulating system.

Foreign Medicine.

State of the Medico-Legal Doctrines concerning Insanity in Germany. By M. Taufflieb.

(Continued from page 184.)

2. *Antecedent Diseases.*—Hypochondriacism, hysteria, epilepsy, the puerperal state, are morbid conditions, that, in the opinion of all psychological physicians, facilitate the development of instinctive monomania. Whenever, therefore, any of these diseases has been ascertained as exciting in a person accused of a crime, the circumstance has always been of considerable importance in the eyes of the medical jurist, particularly in cases where the very nature of the outrage gives cause for suspecting a lesion of the mental faculties. Such was the case in the instance of a young incendiary, in whom epileptic symptoms had preceded the outbreak of monomania, and whom the Berlin medical council considered as not being a free agent, and incapable of discernment at the time of the act. Among the facts on which this judgment was founded, stress was especially laid on the epileptic symptoms, to which the patient was subject, and which are known from experience, frequently to alternate with certain derangements in the intellectual functions.

3. *The actual physical symptoms*, which announce certain lesions in the digestive functions, and the circulation, have been also regarded, and with justice, as capable of furnishing important data respecting the mental condition of the person to be examined. The majority of German physicians have ever had a care to refer in their reports to the influence exercised over the nervous system by chronic affections of the intestinal canal, certain derangements of the circulation, such as irregular menstruation, affections that might induce secondary disorders, such as sanguineous congestions of the head, &c. These various alterations are recognised by a series of symptoms that cannot escape the intelligent physician. Doubtlessly these pathological phenomena are not necessarily so much connected with the existence of monomania, as that it shall be sufficient merely to ascertain the former in order to admit the existence of the latter; yet, as they have been observed in

the majority of monomaniacs, it cannot be denied that their presence in doubtful cases of mental alienation may become vastly important in corroborating the value of many other circumstances that tend to throw light on the medico-legal investigation. Their coincidence, for instance, with the age of puberty in a young incendiary, who was known to have acted without any motive of malice or interest, may lead, in some cases, to positive conclusions; and this has actually been found to obtain in several medico-legal trials recorded in various works*.

4. *The character and habits of the accused* may also furnish valuable means of distinguishing the really diseased man from the criminal. The appreciation of this kind of symptoms does not belong exclusively to the judge, as might be thought, and has been asserted. As mental diseases cannot in general be ascertained by merely material investigation, the physician must have recourse to those of another order if he fulfils his task satisfactorily. In fact, some of the best indications of the disease are to be found in the antecedent conduct of the monomaniac, and, he may from them, be proved to have been induced to an act of which he was naturally incapable. We may imagine a villain killing without motive, and from mere cruelty; but how great is the difference between the habits and character of such a one, naturally ferocious as he is, and the habitual behaviour of the unfortunate monomaniac, who may very frequently be cited as an actual model of mildness and prudence.

5. *Absence of precaution* in the performance of the act, is another thing that distinguishes the man urged on to murder by a disease, from him who acts freely, and with discretion. Were the monomaniac able, in certain cases, I do not say to restrain himself from killing or setting fire, but only to stay, for an instant, the moment pointed out for the explosion of his fury, he clearly would not choose for the purpose of killing, a time when, for instance, he was surrounded by persons ready to seize him, or for the purpose of setting fire, the open day, and a house filled with active persons, who would be able to extinguish the fire immediately. Made-

laine Klein, aged seventeen, entered the house of M. Becker, at Miesenhein, as a servant, on the 7th of February, 1834. In this house, fire broke out at the following periods:—the 12th of February, in the evening; the 13th, at eight o'clock in the morning; the same day, between ten and eleven in the morning, and between two and three in the afternoon; and on Sunday, the 15th, at three in the afternoon. These repeated, and frequent attempts, at firing, coinciding with the entrance of the girl Klein, necessarily led to the author of them, who indeed could not have taken more effectual steps to betray herself. The Beckers immediately sent the girl back to her friends, not as a criminal, for they could not suppose any intention on her part to do harm, but as insane and "bewitched," to use their own expression. Sometime after, she went into another service, but very soon after, fire broke out in the house of her new master in the morning, and unfortunately, raged so quickly as soon to reduce it to ashes. Suspicion fell on the girl Klein, and she readily confessed herself the author of the various fires, at the same time that she bitterly deplored the mischief she had committed. A trial was instituted, but the existence of an instinctive monomania was very soon proved in this unfortunate girl*.

6. *The absence of all motive* is what more particularly marks the act of the monomaniac. Not only are they unable to promise themselves any advantageous result of their acts of violence, but on the contrary, frequently deprive themselves of all they hold dearest in the world. All medical jurists have paid especial attention to this peculiarity: no doubt, this circumstance it was which gave the first notion of the existence of an instinctive monomania, confirmed, as it has since been, by a lamentable number of instances. The cases in which the appearance of criminal motives coincides with the existence of a real monomaniac, may present great difficulties, and require the physician to have recourse, in these circumstances especially, to all the other signs that enlighten his researches.

Such are the characters of instinctive monomania, to which the attention of medical

* Clarus, Beitrage zur Eskenntnis, &c., Leipsic, 1828.—Henke's Journal, 1825.

* Henke's Journal, 1825.

jurists have been more particularly called, and on which many of the medico-legal decrees in Germany have been based. By keeping them constantly in view, I hold it will be possible to avoid, in the majority of cases, the grievous mistake of congregating men morbidly affected, with others that are actually criminal, and vice-versâ.

Rational Monomania, or Partial Insanity.—According to M. Esquirol, this disease is “that kind of lunacy in which the insane person, retaining the use of almost this entire reason, is only delirious on one object, or a limited number of objects, feeling, reasoning, thinking, and acting in other respects as he felt, thought, and acted previous to his malady.”

The first question that presents itself in the examination of this subject is—*when is there partial delirium?* or in other words, *how far can a deep-rooted, but erroneous conviction regarding one or several objects, be made to constitute a real monomania?* I go to show how this question is handled and solved in Germany.

M. Hoffbauer makes monomania consist in a vicious relation between the senses and the imagination, that causes the fictions of the latter to be taken for real impressions. This definition has been considered incomplete, since it does not include all the conditions of insanity. The vicious relations mentioned by Hoffbauer may exist without any necessary disturbance of reason arising. Professor Clarus, who has more particularly dissented from this definition, relates, among other instances, that of a well-educated man, who was night and day tormented with all manner of auditive illusions, by voices now near, now distant, that sometimes called him by name, at other times abused him, &c.* Very frequently it was with the greatest difficulty that he persuaded himself that the sounds were illusory, and sometimes he found it impossible to attribute them to other than real impressions. Yet M. Clarus does not consider this man as monomaniac, because he did not present the essential characteristics of that state to be hereafter mentioned.

M. Henke considers monomania in pretty nearly the same light as Hoffbauer. With

him the disease is characterized by the incapability of distinguishing internal and purely subjective sensations from external, objective impressions; this error being the starting point of the extravagant acts to which the monomaniac is driven.

M. Clarus does not consider the illusions of the senses and hallucinations as a positive and characteristic sign of monomania: “these hallucinations,” says he, “may become a source of error and false judgments, but do not necessarily produce partial insanity.” According to him, monomania only exists when the fictions of the imagination take exclusive possession of the intellect, cross it in its operations, cause it to lose sight of the relations that ought to be taken into consideration, and in this manner disturb the rectitude of the judgments. Thus an erroneous conviction, however deep it may be, does not suffice to constitute a mental malady even in those cases where this conviction originates in some perversion of the perceptive and sentient faculty. More than this, the error must have so entered into the mind, as to exercise an absolute command over it, and mar the free exercise of the intellectual functions.

In order more lucidly to develop the great psychological and medico-legal question before us, it will not be without utility to review a certain number of cases of monomania developed under the influence of different moral conditions; this will enable us to observe how far the principles laid down find applications in practice.

First Case.—A woman, for some time a prey to domestic griefs, planned putting an end to herself. Not, however, having the courage to commit suicide, she thought of setting fire to a house, in order that she might be condemned to death. She put this into practice, and immediately went to acquaint a magistrate of her crime. Was this woman in a state of mental alienation? Several physicians have endeavoured, in similar cases, to demonstrate the existence of monomania by leaning on the very nature of the criminal fact, which they look upon as a proof of insanity. This opinion is refuted by the argument that the act was not in itself absurd, since it was adapted to the fulfilment of the end for which it had been committed. Besides, according to the prin-

* Henke's Journal, 4th Supplement, 1824. VOL. VIII.

ciples above advanced, even an irrational action is not rigorously sufficient to prove the existence of mental alienation. But if it be considered that suicidal desires themselves suppose a perversion of the intellectual faculties—constituting the variety of monomania to which M. Esquirol has given the name of *lypmania*—the question is limited to the inquiry whether the desire to take her own life arose in any lesion of the mental faculties. In this light it was that the question was viewed by Dr. Pfeuffer, of the Bamberg hospital, who was charged with the investigation of this woman's case. The result of his inquiries did not prove the existence in this woman of a confirmed monomania, but of a melancholy of sufficient intensity to prevent the free exercise of the intellectual faculties. He, however, was of opinion, that though she ought not to suffer the utmost rigour of the law, she should, nevertheless, be severely punished, since it cannot be maintained that she acted without any discernment whatever.

Second Case.—Platner gives an account of a young man who killed his comrade with a pistol shot, imagining that the latter was endeavouring to put an end to him by sorcery. He was well aware that the punishment of death awaited him; "but," said he at the bar, "a thousand times better to die on the scaffold than miserably perish by magical arts." This man Platner pronounced to be affected with monomania, and his opinion was fully adopted by the Leipsic faculty. Now it is to be remarked, that the existence of monomania was here admitted not because the man had acted from an imaginary motive based on a popular prejudice (a prejudice, moreover, of very ordinary occurrence, and perfectly compatible with a normal condition of the mental faculties), but because this chimerical fear had obtained such dominion over him, that far from being stopped by the fear of capital punishment, he saw in it a preferable prospect to the lingering and cruel death by which he imagined himself to be threatened. This wretched man's case was similar to that of those maniacs whose homicidal fury is provoked by a false and inappropriate application of the right of self-preservation.

Third Case.—A woman that had been long tormented with violent fits of jealousy, at-

tempted to kill the servant girl, whom she suspected of having a liaison with her husband. The murder had been perfectly premeditated; she had induced the girl to enter a certain room, and there, aided by a man, whom she payed to assist her in the execution of her design, she placed a rope round her intended victim's throat to strangle her. Happily, the girl freed herself from her grasp by a sudden movement, and saved herself by leaping through the window. Dr. Elwert in his report on this woman's case, does not endeavour to prove that the jealousy itself was an excuse for the deed; but he goes to shew that passion long cherished and brooded over, had altered the intellectual faculties of the accused, and induced an actual monomaniac state*.

Fourth Case.—Pyl gives an instance of a woman habitually tormented with religious scruples, who killed her neighbour's child, to whom she was much attached: "death alone," she said, "can withdraw this child from the seductions of the world—you ought therefore to kill it." This woman was looked upon as a monomaniac; I have introduced the case here, in order that, as a case of evident monomania, it may be compared with the following case, which appears to me perfectly analogous, but which has been judged very differently.

Fifth Case.—Peter Nielsen, a journeyman joiner of Slagelse (Denmark), on the 27th of April, 1827, drowned his four youngest children, whom he tenderly loved, in order to save them from the misery of beggary. This man was generally esteemed for his prudent conduct and peaceable disposition, as was testified by his neighbours at his trial. For some time the bad state of his affairs had preyed on him, and the supposed approach of beggary drove him to despair. The following thought, thus expressed by himself, was ever before him: "you must keep your poor children from the misfortune that threatens them, by putting them to a death that is a thousand times preferable;" following up this thought, he committed the horrid deed. Immediately after the act thus committed under circumstances which supposed some degree of reflexion on his part, Nielsen calmly went and ac-

* Henke's Journal, 1834.

cused himself to the magistrates, without expressing the smallest regret. The indictment was framed, but the question of monomania was altogether avoided. Nielsen, it was said, ought to have resisted the horrid idea that drove him to the murder. The accused confined himself to a declaration that he considered it was for the welfare of his own dear children that he had brought them to so cruel an end; he was condemned to death, but the sentence was commuted to perpetual imprisonment. Comparing this case with the fourth, on the principles of monomania above laid down, we arrive at similar conclusions. It may be remarked, that in both cases the perpetrators of the murder believed that they were acting for the benefit of their victim; if this consideration saved one, it ought to have saved the other. The woman spoken of by Pyl, a slave to fears on the subject of religion, had fallen into a real state of monomania; had not the unhappy father also his reason disturbed by fears concerning the future lot of his children? Had not his mind been led astray by a morbid degree of paternal tenderness, would he not made had such reflexions as these?—Death is not the only means of rescuing my children from the misfortunes with which I believe them to be threatened; at a future time they may find in the labour of their bodies, resources that will place them above the beggary that I presage. That such simple and natural reflexions should not occur to a man, his intellectual faculties must have been necessarily bound down and confined by a fixed idea—in other words, he must have been in a state of confirmed monomania. Similar considerations caused monomania to be admitted in the woman of Case 4; in fact it was easy to see that exaggerated fears for the future fate of her child had mastered her reason so as to make her lose sight of the most simple reflexions, and feel the absurdity of her conduct. True, she was at the same time led astray by another fear—that of failing in the accomplishment of her supposed duty; but in analysis this other cause of mental alienation differed not from that of Nielsen.

On reflecting on the different varieties of monomania that we have passed in review, it appears to me, that we may admit the

following conclusion. In order to establish partial delirium in a patient, his intellectual faculties should be shewn to be actually governed by an idea, which at the onset may not have been absurd; whilst eccentric thoughts, erroneous convictions, vicious relation of the senses, and all the illusions dependant thereon, are to be considered as insufficient to constitute in themselves a real monomania.

Reviews.

A Treatise on Pulmonary Consumption; comprehending an Inquiry into the Causes, Nature, Prevention, and Treatment, of Tuberculous and Scrofulous Diseases in General.
By James Clark, M.D. F.R.S. 8vo. pp. 399. London: Sherwood & Co.

(Concluded.)

CHAP. IX is on *Tuberculous Diseases in Animals*. The more extended cultivation of comparative anatomy and physiology, of late years, is gradually preparing the way for what may possibly turn out a very important branch of medical knowledge—*comparative pathology*; nor is it at all unlikely that, at some more advanced period of science, a comparison of the effects of therapeutical agents on the system of different animals may throw much light on the theory and practice of medicine. If a practitioner of human medicine were to undertake to cure his horse of pneumonia, nothing would be more natural than that a part of his treatment should consist in the exhibition of a strong cathartic; but he might be somewhat surprised at an occurrence extremely familiar to veterinary practitioners, namely, an immediate metastasis of the inflammation to the intestines, and the speedy death of the animal from acute enteritis: such is the variety of relation between different parts of the economy in different animals, and such the diversity in the operation of medicines upon them. Dr. Clark's chapter on tuberculous disease in animals is an interesting one, and we hope that succeeding authors will follow his example in drawing from the resources of comparative pathology, whenever the subject admits of it. We shall

make no apology for extracting nearly the whole of this chapter.

"Tubercles have been found in many orders of the mammalia, carnivorous and herbivorous, in birds, in reptiles, and perhaps in insects:—among the mammalia, in the lion, dromedary, antelope, deer, horse, cow, sheep, goat, domestic pig, monkey, guinea-pig, hare, rabbit, squirrel, and porpoise; among birds, in the psittacus erythacus, and some other macaws and parrots, in the flamingo, turkey, house-sparrow, and domestic fowl. Mr. Owen, Assistant Curator of the Museum of the Royal College of Surgeons, informs me that he has discovered tuberculous disease in the following animals, which died in the gardens of the Zoological Society:—*felis caracal*, *Persian lynx*; *felis tigris*, *tiger*; *paradoxurus typus*, *paradoxure gennet*; *viverra Rasse*, *civet cat*; *herpestes mungos*, *Indian ichneumon*; *nasua fusca*, *brown coati mundi*; *ursus Thibetanus*, *Nepdl bear of the Himalaya Mountains*; *tapirus Americanus*, *American tapir*; *alces Americanus*, *American elk*; *simia satyrus*, *ourang outang*; *Macacus cynomolgus*, *Macaque monkey*; *M. radiatus*, *bonnetted monkey*; *M. Rhesus*, *pig-tailed monkey*; *cercopithecus sabæus*, *green monkey*; *papio maimon jun.*, *Mandrill baboon*; *lemur nigrifrons*, *black-fronted lemur*; *lemur macaoco*, *ruffed macaoco*; in an *Eskimaux dog*, and in the lungs of a large serpent (*Python tigris*).

"The morbid appearances presented on examination of the animals enumerated, bear a close analogy to those observed in man: the lungs, spleen, mucous membrane of the intestines, the liver, mesenteric, bronchial, and lymphatic glands, are the organs most frequently affected. We are, however, better acquainted with the morbid anatomy of monkeys, because, of all animals, that family is most subject to tuberculous disease; indeed, nearly all the monkeys in our menageries die tuberculous. Dr. Reynaud, of Paris, has made some interesting researches in this department of comparative pathology, and has published an excellent memoir on consumption in the monkeys at the Jardin des Plantes. In fourteen of these animals he found the lungs containing tubercles, and in many cases they were almost entirely converted into tuberculous matter. In three monkeys the disease was confined to the lungs exclusively; in the others various organs were affected. The larynx was ulcerated in two cases; the bronchial glands were always more or less tuberculous, and, in one instance, they were so much enlarged as to obliterate the left bronchus, and prevent respiration in the corresponding lung, which was much contracted. The spleen, in six cases, was much diseased, being enlarged and adherent to the peritoneum. The blood in the cells formed reddish clots, in

the midst of which were tuberculous points. The tuberculous disease was found in various stages of softening, and sometimes there were caverns lined with a false membrane. In one case the tubercles in the lungs were isolated and crude, while in the spleen they were large and softened in the centre; showing that the spleen was the organ in which the tuberculous matter was first deposited.

"As in the human species, so in animals the disease occurs at all ages. MM. Andral and Dupuy have even observed it in the fœtus of the sheep and rabbit.

"My friend, Mr. Newport, a comparative anatomist of great promise, whose name is already favourably known by his researches into the minute anatomy of insects, has favoured me with an account of what he believes to be tuberculous deposits in that tribe. In the larva of the sphinx ligustri, or common privet moth, he met with a peculiar matter disseminated in small, irregular, aggregated masses, white, opaque, and of a cheesy consistence, over the whole internal surface of the insect, between layers of very delicate cellular tissue. These masses were most numerous among the muscles; on the exterior of the alimentary canal, particularly the stomach; on the secretory silk glands, in the biliary ducts, and on the nerves. In the carabus catenulatus, or ground-beetle, and in the staphylinus olens, both carnivorous feeders, he noticed similar deposits of more uniform and much smaller size in the cellular and pulmonary tissues: he also detected appearances similar to those observed in the sphinx ligustri, in the common cray-fish, the astacus fluviatilis of Leach. It is worthy of remark, that the sphinx was fed upon stale leaves of the privet for some days previously to examination, the unusual wetness of the season having prevented a fresh supply."

Our author has received the following additional observations from Mr. Newport.

"The concrete matter which I believe to be tuberculous is deposited chiefly between the layers of cellular tissue which surrounds the muscles, and exists throughout the whole body of the insect: it is in the form of irregular, opaque, white masses, or granules. It sometimes occurs in the secretory organs, where it is much softer than when disseminated through other textures, and is of an opaque, white colour, very different from that of the natural secretions. When found in the salivary vessels, and in the rudiments of the ovaries in the larva, it occurs in small patches, and in some specimens it has been observed in the salivary vessels only. The skin of the diseased insects (if in the state of larva) is generally slightly discoloured, dry, and shrivelled; and they are deficient in the plumpness of healthy individuals. In order to observe this substance, the insect should be placed

in alcohol for a few days, during which time the matter becomes hardened, and is more readily distinguished from the fat and different textures.

"From the result of an experiment upon the larvæ of the *sphinx ligustri*, I am led to conclude that these depositions in insects may be produced almost at pleasure. About eighteen or twenty larvæ of this species, collected just after entering their last skin, were confined in a box closely covered and kept, uncleaned, in a room the temperature of which ranged from 65 deg. to 80 deg. Fahrenheit, and were supplied with food of deteriorated quality. By this means their growth and the period of their changing were retarded. In order to produce a sudden impression of cold upon them, they were repeatedly plunged into cold water. The result was, that in the whole of them deposits were found, and generally in the secreting organs.

"Whatever may be the nature of this substance, it does not appear to be very common, in favourable seasons, in the larvæ of the sphinx while in their natural haunts. Upon examining many specimens, apparently quite healthy, soon after collecting them, I could find but few, perhaps scarcely one in ten, in which the disease was conspicuous.

"Since making these observations, I have discovered the disease in the common shrimp (*Cancer crangon*: Linn.), and in the scarce oil-beetle (*Meloë cicutricosus*: Linn.), both of which are vegetable feeders, the former feeding upon fuci and sea weed, and the latter upon the wild ranunculi, taraxicum, &c. The shrimps were collected from their natural haunts, and immediately placed in alcohol for preservation: upon examination some months afterwards, I found the disease more common in these instances than in any I have yet met with. The matter was disseminated in small granulated masses through the whole body, even within the substance of the nervous columns. In the *meloë* the masses existed upon the alimentary canal, hepatic vessels, and within the trachea, and there was one large mass, much softer than the others, within the substance of the right supra-oesophageal ganglion, or brain, occupying at least one third of the ganglion itself."

As Dr. Clark observes, the existence of tuberculous disease in insects requires to be confirmed by further observations; those just quoted are, nevertheless, highly worthy of the attention of pathologists. The following note is appended to this chapter.

"All the milch cows in Paris, and no doubt elsewhere, become tuberculous after a certain period of confinement. I have been informed, that for some time after the disease has commenced, the quantity of milk obtained is greater than before, and

that their flesh is more esteemed by the unsuspecting epicure than that of the healthy animal. A circumstance of the same kind is mentioned by Aristotle, who observed tubercles in the pig, the ox, and the ass; in regard to strumous pigs, he says, that when the disease (*grandines*) exists in a slight degree, the flesh is sweeter (*caro dulcior est*). *Historia Animalium*, lib. viii, cap. 21."

Our author seems here to have mistaken Aristotle's meaning. The tubercles of pigs, alluded to by the Greek philosopher, are not the tubercles of modern pathology, but a disease peculiar to pigs: χαλαζονται δε μονον των ζωνων αν ισμεν υς. (*Hist. Animal*, viii, 21, Ed. Du Val.) This is represented as occurring chiefly on the legs, the neck, the shoulders, and under surface of the tongue. A disease, *κρανγος*, which the Latin interpreters render by the word *struma*, is indeed mentioned as occurring in pigs and in oxen; but in neither is it represented as at all similar to scrofula: in pigs two diseases are called by this name, *pain and heaviness of the head*, and an *incurable form of diarrhæa* (viii, 21); in oxen the disease thus named is stated to consist in increased heat of the breath and frequency of respiration, and to be analogous to *fever* in the human subject: ο εστιν εν τοις ανθρωποις πυρετος τουτο εστιν εν τοις ζουσι το κραυραν (viii, 23); it is added, that the animal soon dies, and that on dissection the lungs are found putrid; in fact, the disease in question appears to be acute inflammation of the lungs.

Chap. 11 treats of the *Pathology of Consumption and Tuberculous Diseases in general*. In that condition of the system which constitutes the tuberculous cachexia, a peculiar matter is deposited by the extreme vessels in various tissues of the body, and this matter, however its appearance may be modified by the structure of any particular tissue, presents certain characters by which it may generally be recognised.

The disease of which the presence of this matter constitutes the distinctive anatomical character, has been variously named in different parts, as *scrofula* in the external glands and the bones, *phthisis* in the lungs, *tubes* in the mesenteric glands, &c.

"This matter, however denominated, is now generally considered by the best pathologists as a morbid unorganizable product, having for its remote or predisposing cause a cachectic state of the general system, and for its immediate production some anomalous

action of the vessels of the part in which it is deposited, but with the nature of which action we are not acquainted. No constitution, no temperament, age, sex, or race, as we have already seen, is entirely exempt from the liability to this disease, although the disposition to it is strongest in that condition of the body called lymphatic, in the age of infancy, in the female sex, and in the negro race.

"In whatever light we may regard tuberculous cachexia, we shall find that its phenomena are explicable only by admitting that it depends on a general modification of the whole animal economy; and that the notion of its being the morbid degeneration of any organ or tissue, or of any particular system, or the morbid modification of any single fluid, is founded on limited views of its nature and laws. The deposition of tuberculous matter in any of the tissues or organs of the body is the result of previous changes in the general system, cognizable, as I have endeavoured to show (Chap. I.), by the physical condition of the patient—a condition quite distinct from mere debility, and therefore inexplicable on the idea of a difference of force or tone of the system; and which, though very generally accompanied with a feeble organisation, is not inconsistent with too great development and inordinate action of particular parts, and even with considerable physical power of the system.

"The universality of the peculiar condition of the system just referred to, necessarily modifies the structure of every part, the nature of every fluid, and the qualities of every secretion. The osseous system is more spongy; the muscular is flaccid and imperfectly developed; the cellular tissue is singularly lax; the vascular system is weak and irregular in its action, and is subject to local congestions from the slightest causes; the skin is generally thin and soft, or thick, coarse, and dry, and is affected by various diseases, apparently arising from the morbid condition of its function of secretion, which, in tuberculous subjects, is always more or less deranged. The mucous system is peculiarly susceptible of disease; and, on the application of the slightest causes of irritation or congestion, matter, differing more or less from the healthy secretion, is poured forth in large quantities from the surfaces of the mucous membranes. The blood is serous, and deficient in fibrine and colouring matter. The lymphatic system, being more intimately concerned in the function of nutrition, is more peculiarly affected; and hence it has been by many considered as the original seat of the disease.

"These morbid conditions of both fluids and solids are examples and proofs of a defective organisation. In the healthy state of the nutritive function each part separates the materials proper for its nutrition, and converts them into its own particular tissue

or structure; and the various secreting organs secrete their peculiar fluids—some to be applied to the purposes of the animal economy, others to serve as vehicles for eliminating effete and useless matter from the system. It is necessary to the maintenance of health that both these functions—the nutritive and excretory—should be performed in a certain ratio; and thus it may happen that imperfect assimilation on the one hand, or defective secretion and elimination on the other, shall give rise to such a disordered state of the constitution as may ultimately terminate in tuberculous cachexia.

"This comprehensive view of the nature and causes of tuberculous cachexia, and of its influence on the secretions and on the products of diseased action, leads to the conclusion that tuberculous deposits are always at first fluid, and that the concrete form, in which they are commonly found, arises simply from the absorption of the more fluid part, and is in many situations dependent chiefly on compression, as is shown (p. 122); and I have no difficulty in conceiving that the matter formed in certain cutaneous eruptions, and that thrown off from the free surfaces of mucous membranes, would have assumed all the characters of crude tubercle, had it been confined in the parenchyma of organs, or the extreme bronchial ramifications, &c."

Dr. Clark has some original views with respect to the production of tubercles, which he introduces by expressing his willingness to incur the imputation of yielding a little to theory, rather than leave unsaid that which he believes may be of practical value to his readers. He is perfectly right: theory is indeed too much decried in the present day, by certain persons who style themselves "practical men," the English of which sometimes is, "men who cannot think;" all discoveries are theories till they are established by facts, and he who never entertains a theory, can never be an intelligent observer or experimenter, for he has nothing to direct his observation in one channel rather than another; theory is pernicious only when misused—when mere probability is allowed to usurp the place of demonstration.

"It is reasonable to believe," says our author, "that the remote causes of consumption and of tuberculous disease in general, however various their mode of operation may appear, act by inducing some peculiar or determinate derangement of the system—some positive pathological condition or conditions, which, being constantly present wherever tuberculous disease is found, may be regarded as necessary to

its production. Although I readily admit that we cannot fix on any pathological condition, the presence of which is absolutely necessary to the production of tuberculous cachexia, there is one so very generally present, as in a practical point of view to demand our especial attention. I allude to a state of congestion of the venous system of the abdomen, which has been termed abdominal plethora.

"In the present defective state of our knowledge of the laws which regulate the animal economy, we can neither trace the various functional disorders which lead to abdominal congestion, nor understand the processes which connect it with tuberculous cachexia. But although we cannot perceive every link of the chain, we have, I am persuaded, a good notion of the chain itself. It is not, I think, difficult to understand how abdominal plethora, by impeding the functions of the nutritive organs and diminishing the power of the circulation, should lead to a state of general cachexia, and how cachexia should lead to the deposition of tuberculous matter. But whether it be understood or not, it is a matter of fact that abdominal plethora is an almost constant concomitant of tuberculous cachexia.

We are doubtless ignorant of many of the morbid conditions in the animal economy which combine to give a determinate effect to abdominal plethora; but the causes which are well known to give rise to the disordered state of health which precedes and leads to tuberculous cachexia, and the most successful means of correcting this, alike support our opinion of the presence of abdominal congestion, and afford a rational explanation of the phenomena of the disease.

"Congestion of the venous system of the abdomen has long been regarded as a fruitful source of disease. It was familiar to the pathologists and physicians of the last century, and, although less attended to, has not been overlooked by the moderns. Such of my readers as are conversant with the writings of the German physicians of the middle of the last century, particularly Stahl, Hoffmann, and, above all, Kaempf and his disciples, will be aware of the extensive influence of this state of the abdominal circulation, and the importance attached to it at that time. Referring to those works where the facts upon which the doctrine rests are fully exposed, I shall confine myself to a few remarks more particularly bearing upon my subject, and which it is but justice to myself to say were established in my mind, as the result, or supposed result, of observation, before I became acquainted with the German doctrines of abdominal infarctus.

"Of the various phenomena presented by a person strongly predisposed to or labouring under tuberculous disease, a congestive state of the abdominal venous circulation will, I believe, be found, on close

investigation, to be one of the most constant. In children originally of a strumous habit, we observe a constant disposition to this congestive state of the abdominal circulation; and unless we succeed in obviating it, they become tuberculous, and die early in life. In youth we find the same state of congestion as a precursor of tuberculous cachexia; at this age it manifests itself often by epistaxis, by hemoptysis, and even by hemorrhoids; but it is during the middle period of life, from thirty-five to fifty, that it is accompanied with more marked symptoms, such as dyspepsia and its various concomitants, which exist often for a very considerable time, and not unfrequently obscure the pulmonary affection till tuberculous disease has made extensive progress.

"Congestion and disordered function of the abdominal viscera have long been remarked as causes of consumption: they were regarded by Kaempf and his disciples as giving rise to most of the chronic diseases of the chest. Portal and several other foreign authors have also remarked the connexion of consumption with abdominal disease, but in a manner so vague and undefined as to attract little attention. In this country, likewise, several authors have noticed the congestive state of the abdominal circulation, more especially congestion and deranged function of the liver, as a frequent source of similar disease; among these authors may be particularly mentioned Mr. Abernethy, Dr. Wilson Philip, and Dr. Ayre; and, more recently, Dr. Todd, in his comprehensive article on 'Indigestion,' already referred to, has given in his pathology of *strumous dyspepsia*, views corresponding exactly with those just stated. 'The phenomena of this disease,' he observes, 'its whole complexion and character, sufficiently indicate a congestive state of the hepatic system; and were we to assume, as the proximate cause of the disease, a plethora of the vena portarum, both in its roots and branches, we should be furnished with the means of explaining all the symptoms of the disease; for we should readily understand how, in this state of the circulation of the abdomen, the mucous surfaces of the intestines should be full of blood, consequently subject to inflammatory irritations and disordered functions, whilst the peculiar office of the duodenum renders it specially liable to be the seat of them: how the function of the liver being deranged, all the other consequences of this disease may follow: for though we may not know precisely what share the functions of the liver have in the process of sanguification, we can easily understand how it may interrupt and interfere with this process, leading to a cachectic state of the fluids, from which result tubercles and other semi-vital and semi-organic productions. Nor does it seem an improbable supposition that a disposition to abdominal

plethora, or an organization which favours it, may be transmitted by parents to their offspring, more especially in dyspeptic and hypochondriacal persons, in whom the chylipoietic viscera, under constant irritation, are necessarily also in a state of congestion: we might thus explain how the strumous cachexia is continued, and how it is generated.

"I do not, however, wish it to be inferred," continues Dr. Clark, "that I consider abdominal congestion as a pathological condition that must necessarily be followed by tuberculous disease. In strong and healthy constitutions nature has provided processes in the form of diseases for the relief of this morbid condition, of which gout, hemorrhoids, and cutaneous diseases offer the most ready examples. When nature or the constitution has not power to operate these corrective processes, that morbid condition is induced by abdominal plethora which leads to the formation of tubercles. The stronger children of gouty parents inherit the gout; the more weakly become tuberculous. In the history of the diseases of families, it is matter of common occurrence to observe the gouty constitution gradually degenerate into the tuberculous. On the other hand, neither do I mean to maintain that the morbid condition of body which precedes the formation of tubercles must necessarily be preceded by abdominal plethora. We can easily understand how that morbid condition may be brought about without the intervention of abdominal plethora. All I contend for is, that in the ordinary course of civilized life it is the most general mode by which tuberculous cachexia is induced, and on that account the most important to be known. Of the various other conditions of the system which may contribute to the production of tuberculous cachexia, little is known: I have already noticed as a very probable predisposing cause, a feeble heart—a condition which a congestive state of the venous system tends strongly to augment."

The three remaining chapters treat of the prevention of consumption and tuberculous diseases in general—of the treatment of tuberculous cachexia—and the treatment of pulmonary consumption. These are points of vast practical importance, but which do not afford much scope for original observation. Many judicious remarks will be found on the most probable means of preventing the tuberculous diathesis from developing itself into actual disease, and on the various remedial agents recommended by different practical writers in consumption. On *blood-letting*, Dr. Clark gives the following as his general opinion.

"The employment of general bloodletting,

and even the local abstraction of blood, in consumption, requires, in my opinion, great judgment and circumspection. The more general error is the abstraction of too great a quantity of blood at a time; treating the disease as if it were a purely inflammatory one, and forgetting that the inflammatory symptoms are merely consecutive upon tubercles, and that the constitution of the consumptive patient is little capable of replacing the blood too often lavishly drawn. But keeping clearly before us the condition of our patient, the nature of his constitution, and the pathological condition of the lungs, and considering that the utmost benefit which we can generally expect or derive from the practice, is the removal or diminution of congestion or inflammation, complicated with and often dependent on the presence of tubercles; keeping all these circumstances in view, blood may be abstracted with advantage at any stage of consumption, when the symptoms require it. 'In the present state of our knowledge,' observes Dr. Carswell, 'there is, perhaps, no practical rule regarding the local treatment of tuberculous affections, of equal importance with that which is founded on the pathological fact of inflammation being the frequent, if not the necessary consequence of the mere mechanical presence of the material by means of which we recognize the local existence of these affections. To protect the individual and the affected organ from the influence of all those agents, internal and external, which tend to create an inordinate degree of excitement, or favour the development of active congestion or inflammation, is the rule to which we allude, and to which there can be no exception in the treatment of tuberculous diseases.' After pulmonary congestion has been diminished by general bleeding, the abstraction of blood by means of cupping or leeches, when further depletion is necessary, has a very beneficial effect."

At the very commencement of phthisis, when the disease is ushered in with slight inflammatory symptoms, we have found no form of bleeding so effectual as the application of two leeches to the chest, repeated daily for several weeks together; a great impression is thus made on the local disease, without any considerable diminution of the patient's strength, an evil most carefully to be guarded against in the treatment of a protracted and wasting disorder.

Our author speaks favourably of the employment of *emetics* in the early stage of phthisis. Having alluded to the statements of Morton, Simmons, Parr, Bryan, Robinson, Reid, Marryat, Dumas, and Bayle, he gives the following statement of the recent experiments of Dr. Giovanni de Vittis, chief

physician to the military hospitals of the kingdom of Naples.

"In the military hospital at Capua, where the greater number of phthisical patients of the army are sent, antimonial emetics were tried in every case. From the 1st of May, 1828, to the 18th of January, 1832, there were sent out of the hospital perfectly cured, '*perfettamente guariti*,' forty cases of chronic catarrh, forty-seven of phthisis in the first stage, one hundred and two in the second, and twenty-seven in the third, making a total of two hundred and sixteen cures, one hundred and seventy-six of which were cases of phthisis. The mode of treatment consisted in giving, every morning and evening, a tablespoonful of a solution containing three grains of tartarized antimony in five ounces of infusion of elder-flowers, and one ounce of syrup. A second spoonful of the emetic mixture was given at the end of a quarter of an hour, when the first dose did not produce vomiting. The patients were at the same time put upon a light farinaceous diet, composed chiefly of rice, chocolate, and biscuits. If the antimony excited brisk purging, it was omitted for some days, and roasted ipecacuan and digitalis, which are said to produce wonderful effects in curing this diarrhœa, were administered in doses of a grain of each, and repeated every hour, or oftener, until the diarrhœa ceased.

"Although we may be permitted to question the permanency of all the cures, especially of those in the advanced stage, we cannot doubt that the practice must generally have produced very beneficial effects."

Dr. Clark informs us, that his own attention was first particularly directed to the use of this class of medicines in consumption, by the researches of Dr. Carswell.

"I have already stated, as the result of Dr. Carswell's researches, that tuberculous matter is first deposited on the free surfaces of mucous membranes, in all those organs into the structure of which they enter. In the lungs, the extreme branches of the bronchi and the air-cells form the primary and principal seat of tuberculous matter; from the structure of these parts, also, it is most likely to be retained. To prevent such accumulation and retention is a matter of the greatest importance. Now the power of emetics in augmenting and ejecting the bronchial secretion is well established; we can conceive, therefore, how the repeated action of emetics may prevent the deposition, or at least the retention, of tuberculous matter in the bronchial ramifications and air-cells, and thus prevent the localization of the disease, and give time for the correction of the constitutional disorder. The utility of emetics, in cases of threatened consumption, may be thus partly explained,"

Dr. Clark believes emetics to be useful, not merely by their action on the pulmonary system, but also by their giving freedom to the cutaneous circulation, promoting the biliary and other secretions, which are usually deficient in the tuberculous constitution, and diminishing abdominal congestion.

"The choice of emetics, the period of employing them, and the frequency with which they may be repeated, are not matters of indifference. Morton preferred, and generally prescribed squills; that used by Marryat, and called by him the "dry emetic," consisted of one grain of tartar emetic and three of ipecacuan, taken fasting, without drinking any liquids during its operation. When the diarrhœa was severe, his emetic consisted of four grains of ipecacuan and one of sulphate of copper. Dr. Senter prefers this combination of sulphate of copper and ipecacuan; he considers it one of the most safe and efficacious emetics in the *Materia Medica*. He gave from seven to ten grains of each in the morning fasting, and, if necessary, increased this dose. Reid preferred gentle doses of ipecacuan, sufficient to cause puking once or twice; and Simmons recommends sulphate of copper as superior to any other. Ipecacuan is, perhaps, the safest emetic for repeated use, although it is uncertain in its operation, I fear often owing to the difference in the quality of the drug. The emetics which act most quickly, such as the sulphate of zinc and sulphate of copper, would be the kind of emetics best suited for consumptive patients. The emetic should be so managed as to produce a very gentle effect, and a small quantity of fluid only should be taken to promote its action. For this purpose, tepid chamomile tea is particularly well suited. When the biliary system is much loaded, an antimonial emetic may be useful in the first instance, as it appears to possess more power than other emetics in promoting a free discharge of bile."

Dr. Clark adds, that his own experience of the operation of emetics has not yet been very considerable; its results, however, are such as to induce him strongly to recommend their further trial.

We must here conclude our review of this admirable work, which we do not hesitate to pronounce the best that has yet been published in this country on the subject of consumption. As such, we beg leave strongly to recommend it to the attention of our readers.

A Manual of select Medical Bibliography, in which the Books are arranged chronologically according to the Subjects and the derivations of the Terms, and in which the nosological and vernacular Synonyms of the Diseases are given; with an Appendix containing Lists of the collected Works of Authors, systematic Treatises of Medicine, Transactions of Societies, Journals, &c. &c. By John Forbes, M.D.F.R.S. one of the Editors of the Cyclopædia of Practical Medicine, and of the British and Foreign Quarterly Review. Royal 8vo. pp. 403. London: Sherwood, Gilbert, and Piper. 1835.

A WORK of this description has long been a desideratum in British Medical Literature. The profession is much indebted to the author and spirited publishers of this work, for the Cyclopædiæ of Practical Medicine, of Anatomy and Physiology, and we may add, for their forthcoming one of Surgery. These works raise our literature from the humble state in which it was previous to their publication. In France there were five Cyclopædiæ or Dictionaries of Medicine and Surgery, executed by the conjoint talent of the most eminent of the profession in that country, and amounting to one hundred and forty volumes octavo, each containing five hundred and fifty pages. In this country we had two thick volumes octavo, Hooper's and Cooper's Dictionary, admirable works as individual productions.

The spirit of the respected booksellers whose names are at the head of these remarks has led to the elevation of systematic treatises on medicine. They now bring forth a work which has no parallel in our language, and one of great utility to medical practitioners. It not only contains a catalogue of the best British, but also of foreign writers, and will be a work of reference. It is an enlarged republication of the Bibliography of the Cyclopædia of Practical Medicine and its appendix; it is published "with a view of filling, in some degree at least, a very important blank in the medical literature of this country, which has long been felt to exist."

Dr. Forbes has judiciously selected the best works, and properly excluded essays, theses, bibliographical notices, and indexes of medical periodicals. This work consists, as he well observes, of bibliography in the

strict sense of the word, that is, an account of books only. It is on this account he has excluded inaugural dissertations and minor works which are printed but not published (most of them are still born from the press), and also insignificant papers in the Transactions of Societies and medical periodicals. He remarks that some may suppose he has given undue preference to foreign works, but he replies satisfactorily—"But I have assuredly in this particular been influenced by no prepossession in their favour. I have noted the titles of such works as came before me, without regard to the language in which they were written; and if, in several instances, the German and French publications in the list are found to exceed the English in number, the true reason must be sought for in the fact of such publications being really more numerous in the preponderating language. While I have in no instance sacrificed an English work for a foreign one, I have, on numerous occasions, acted on the reverse principle; deeming it but proper, where the choice was limited, that the books in the vernacular tongue should have the preference, in a work intended for the English reader. It is hardly necessary to observe, that in the present condition of medical literature in this country, a bibliographical collection that did not include a fair share of the publications of France, Germany, and Italy, would be deservedly regarded as most imperfect." (Preface, p. vi.) We shall not comment upon the preceding statements, though it would not be difficult to do so. The author apologises for the imperfections in his work, which we must state was unnecessary.

The etymology and synonymy prefixed to the different articles, is a new feature in works of this kind. This will be highly useful to students and young practitioners.

"The greater number of the modern languages of which synonyms are given, are become, in these days, almost necessary acquisitions for the accomplished physician."

Though we highly prize this production, and consider it extremely valuable and interesting, we regret that the author has excluded writers on surgery, obstetrics, and therapeutics. We hope he will at no distant period fill up the blanks to which we allude, and in subsequent volumes complete the work

which he has commenced but left unfinished. We never could recognize the separation of medicine, surgery including obstetrics, and therapeutics; and we feel convinced that the bulk of the profession are of our opinion, and would hail with pleasure a manual of medical bibliography in the full acceptation of the term. Nevertheless, Dr. Forbes has executed his task with the greatest ability as regards medicine in the limited sense; but we trust he will act on our suggestion as regards this science in its most extended scope. In fine, we strongly recommend this work on the ground of utility. It cannot fail to obtain a large circulation, and it eminently deserves it. We have only to add that the synonyms are in Greek, Latin, English, German, Dutch, French, Italian, and Spanish—a polyglot dictionary which will be highly instructive to a large portion of readers.

—o—

A Treatise on Hydrocephalus, with the most successful modes of Treatment. By William Griffith, M.R.C.S.; Lecturer on Midwifery at the Westminster School of Medicine. 12mo. pp. 86. London: Longman and Co. 1835.

THE author of this little work has given a very good account of the nature and treatment of hydrocephalus. His symptomatology is graphic, his etiology comprehensive, his pathology accurate, and his treatment judicious. He has not gone however so comprehensively into the subject as he might have done, though he has executed his task with much ability. The work cannot fail to be useful to junior practitioners, and even the experienced will peruse it with advantage. It shews much ability, experience, and judgment, on the part of its author.

The London Medical AND Surgical Journal.

Saturday, September 12th, 1835.

THE INQUEST ON THE BOY STANY-
NOUGHT—MORAL INSANITY.

A VERY melancholy occurrence which took place in the Edgeware Road on Friday last, affords an illustration of a

form of insanity not hitherto recognised by jurists, and not universally familiar even to medical men: its existence, however, is not the less real; and as the subject is one whose relations to legal medicine are of considerable importance, we take this opportunity of directing the attention of our readers to it. The disorder we allude to is that which Dr. Prichard has aptly denominated *moral insanity*. A variety of insanity consisting in perversion of the moral disposition, unaccompanied by any disturbance of the intellect, was first distinctly described by Pinel, who termed it *manie sans delire*, or *folie raisonnante*. Esquirol recognised the reality of this species of madness; and Dr. Prichard, in his late admirable work on insanity, has given several well marked examples derived from his own experience, and that of other intelligent practitioners. Moral insanity, like derangement of intellect, may influence the general conduct of the individual, or it may be partial, constituting a variety of *monomania*; it may manifest itself by an entire change of character and habits, without any diminution of the reasoning powers; thus a man previously moral and decorous, shall addict himself to every kind of debauchery with a recklessness so extravagant as to induce a suspicion of his sanity, while at the same time he reflects on his degraded condition, and vainly opposes his reason to his perverted propensities; another, naturally of an amiable and generous disposition, becomes morose, selfish, and miserly to such a degree, that his most intimate friends can scarcely recognise the object of their former attachment; yet this man can judge of any question set before him as correctly as at any period of his life. Such cases as these, though recognised by the pathologist as grades of insanity, scarcely admit of being so regarded in the eye of the law, from the impossibility of ascertaining the precise boundary between depravity and disease.

Moral insanity, however, often assumes the more unequivocal form of a gloomy monomania, in which the unhappy sufferer feels himself irresistibly impelled to the commission of some crime of whose enormity he is fully aware—against which he may seek the aid both of reason and religion—and, tossed with the restlessness of an undefined disease, not unfrequently confides his case to the physician. An individual so circumstanced, cannot be held either morally or legally responsible for his conduct—he is a subject for the physician and the divine; and it is gratifying to know that a judicious combination of medical and moral treatment is sometimes effectual in freeing the mind from so fearful a possession; an interesting example of such success may be found in the last number of this journal, on the authority of M. Wildberg, under whose immediate observation it occurred. The case of Mr. Stanynought, alluded to at the commencement of the present article, is evidently one of monomania, and appertaining chiefly to the *moral* form of that affection—not purely so, however, because the patient seems at times to have justified the fatal act to his own mind by a *false process of reasoning*, grounded on the apprehension that his son would become the victim of a malady hereditary in his family, thus evincing a certain degree of illusion of the understanding. The verdict of “wilful murder” recorded by the coroner is clearly wrong; but we do not say this with the smallest intention of reflecting on any of the parties concerned in the investigation; as a coroner’s court is at present constituted, it would not perhaps have been easy to arrive at any other conclusion; the surgeon, however, who was quite correct in pronouncing Mr. Stanynought insane, might possibly have influenced the verdict by explaining the nature of *monomania*, and by stating the fact, which cannot be too generally known to all engaged in such inquiries, that there is a *moral*

insanity which is not necessarily attended with irrationality, but which nevertheless renders an individual unfit to remain at large, and also exempts him from moral responsibility, because his apparent crimes are the result of disease, and his actions are not under the control of his understanding. The coroner’s verdict is of little moment in the instance now before us, as far as regards the life of the prisoner, because if a bill should be found against him by the grand jury, he will no doubt be acquitted on his trial; but there are many cases with respect to which it is highly important that they should not come into court, and this is one of them: the agitation of a trial, or even the suspense preceding it, might easily convert a partial and curable, into an irremediable case of insanity, and an individual whom the resources of art might have restored to health, and the consolations of religion to tranquillity at least, if not to happiness of mind, might thus be condemned for life to hopeless gloom and despondency.

To make a coroner’s inquest what it ought to be, several changes are indispensable. The individual holding the office of coroner should be a man profoundly versed in medical jurisprudence; and though we do not at all agree with our contemporary the *Lancet*, that none but medical men should be eligible to such an office, we think that *cæteris paribus*, a member of our own profession is much to be preferred. Again, a coroner’s jury should not be a common one; it should always consist of intelligent and well educated men, instead of the well-meaning, but uninformed persons who now generally compose it; we have occasionally been quite unable to keep our countenance at the sagacious remarks made by jurors on an inquest.

But the efficient constitution of the coroner’s court can be of little avail, unless the competency of medical witnesses be ensured by a full examination on the principles of state medicine, to

which we hope ere long to see every student subjected previously to his admission into the profession. This indeed is an improvement essential to the honour of the profession, as well as to the administration of justice; since, whatever laurels our brethren may have won, a court of law has very seldom been the scene of their triumph.

DISPENSARIES AND WORKHOUSES—
GRATUITOUS MEDICAL ATTENDANCE.

To the Editor of the London Medical and Surgical Journal.

SIR—I entirely agree with you in the opinion that dispensaries, as conducted at present, are jobs of the grossest description, alike injurious to the public and profession. They are injurious to the public, because they indirectly encourage idleness and vice, and to the profession, because they deprive many of its members of patients well able to obtain medical aid without resorting to any charity, if they only save their earnings from the gin palaces.

Moreover, the new poor law act compels parishes to procure medical aid for their poor; and if this aid were good, which it seldom is, there would be no need for dispensaries. But as the poor law commissioners only employ the cheapest medical practitioner, who is generally poor and needy, the health and lives of the poor are at the disposal of inexperienced individuals. Were the commissioners to employ physicians, surgeons, and apothecaries, as these are now employed at dispensaries in any parish, and reward them for their services, then and only then, the poor would have efficient advice and medicine, dispensaries be rendered unnecessary, and professional rights uninvaded. I am Sir, yours truly,

A GENERAL PRACTITIONER.

—o—

USE OF TURPENTINE IN GONORRHŒA.

To the Editor of the London Medical and Surgical Journal.

SIR—If you deem the following medical fact of sufficient importance, I shall feel obliged by your recording it in your valuable Journal.

In January last, I was consulted by a gentleman who was suffering from a very virulent gonorrhœa, recently contracted, the discharge from the urethra copious, deep-coloured, and fetid, ardor urinæ distressing, and accompanied with severe nocturnal chordee. My usual treatment, copaiba with liq. potassæ, laxatives and sedatives, failed to

afford relief: on the third morning after his application to me, upon the occasion of evacuating the rectum, he found a substance protruding from the anus, which required some effort to disengage, and the force used brought away a portion only of a large-sized tape-worm; I expressed my opinion, that the remaining part, the caudal extremity, was merely lying in the rectum, and would most probably be ejected upon a subsequent evacuation: a careful investigation of the dejected feces could not discover any worm; a troublesome irritation and uneasiness of the anus prevailed, probably more the effect of imagination than reality, which together with the severe gonorrhœal urethritis, was exceedingly distressing to my patient. With a view of dislodging the worm or worms in the intestines, I prescribed half an ounce of spt. terebinth. pur. to be taken horâ somni, which had not the effect anticipated, but a marked and decidedly favourable one upon the urethral disease, for, on the following day the ardor urinæ had nearly subsided, the discharge greatly diminished, and the chordee, which had prevailed so annoyingly for some nights previously, did not recur, in the slightest degree, on the night of the terebinthinate. Impressed with this favourable result, having both objects in view, I advised a repetition of the turpentine on the following night; this night also passed without the slightest chordee, and on the following day the urethral discharge was scarcely perceptible, and merely of a mucous character; no worm passed at this time or since; the irritation continuing in the lower part of the rectum, I pacified my patient by attributing it to the effect of the medicine, which I believe to be the case, and which irritation, no doubt in a modified degree, pervaded the whole course of the alimentary canal, establishing an extensive source of counter-irritation, constituting the *modus operandi* from which the beneficial result derived was to be attributed, analogous to its influence in relieving the peritonitis of puerperal fever, by vicariously inducing increased action and consequent secretion of the vessels of the mucous membrane of the intestinal canal.

This circumstance, purely the result of accident, often the fertile parent of many valuable medical discoveries, has induced me to the adoption of the use of turpentine in many similar cases of gonorrhœa. I have had much difficulty to encounter in its exhibition, from its excessive and permanent nauseousness, and frequent rejection from the stomach; but of this I speak most confidently and unreservedly, when taken and retained, it invariably cured the disease in a period in no instance exceeding eight days, and not followed by the gleet sequelæ so troublesome and almost invariable a remanet of this disease. I tried it in various forms, but the following is best taken, and has proved completely successful:—

R. Olei vel spirit terebinth pur. 3vj;
 Vitellum unius ovi,
 Syrupi papav. albi, 3ss;
 Aquæ destillatæ, 3iv. M. ft.

Mistura—sit dosis uncia, ter quotidie.

I shall be happy to meet, through the same respectable source of communication, a confirmation of the success of this practice from other practitioners. I am, &c.

JOHN LANGLEY.

36, Tottenham St. Fitzroy Square,
 August 24th, 1835.

—o—

MEDICAL BOTANY.

PLATE IV.—ANAGALLIS ARVENSIS.

ANAGALLIS ARVENSIS (common pimpernel). Stem procumbent; leaves three-nerved, ovate, lanceolate; petals dilated at end, crenate with glands. This beautiful little plant, whose sensitive flowers form the peasant's barometer, is frequently called the shepherd's weather-glass, because the corollas never expand in rainy weather, or when the air is moist, but on the contrary, when the atmosphere is dry and the sun shining, they display their scarlet and purple with happy effect, bespangling the earth with their bright eyes in the most agreeable manner, but which is regularly and firmly closed when Phœbus retires to the west.

"The hollow winds begin to blow,
 The clouds look black, the glass is low.
 Closed is the pink-eyed pimpernel.
 'Twill surely rain, I see, with sorrow,
 Our jaunt must be put off to-morrow."

This is one of the wonderful instincts of vegetable nature, for were it otherwise, the damps of the night air would prevent the discharge of the farina from the anthers, and this species of plants would be consequently lost to the link of nature's perfect chain; for although the pimpernel is too lowly to excite the great interest of man, its seed is the food of insects who have their office to perform towards the completion of the general harmony of the globe.

The smaller kind of birds seek this seed with great avidity, and as it is a plant which follows cultivation, it may save a considerable quantity of the seed of the husbandman from the ravages of the feathered tribe.

Like the poppy, the pimpernel is generally found in ploughed grounds, and in gardens, particularly where the air is pure and the soil light or sandy.

The common pimpernel continues to give out a succession of blossoms, from the month of June to the end of September, and is, although a native weed, deserving of a situation on the parterre, its flowers being of a fine yellow scarlet, having a purple circle at the eye, which adds considerably to the beauty of this miniature flower; and

as it is a delicate pretty flower, that we love to see in the small parterre, or on the banks or borders of the larger pleasure garden, we shall observe that it may be increased by cuttings, and when planted in a pot of light earth, and placed in a hot-bed, it will produce flowers in about six weeks.

This little plant, whose numerous branches spread themselves on the ground, being too weak to erect their flower stems, but which catch our attention by the vivid scarlet of the corolla, was formerly in great repute with medical practitioners, although it is now neglected in our practice. It was given in maniacal cases, and even in the hydrophobia, and also as affording relief in cancerous complaints. It appears, however, says Lewis, that it has some claim to the resolvent and detergent virtues ascribed to it by some writers.

—o—

Hospital Reports.

NORTH LONDON HOSPITAL.

Inflammation of the sub-cutaneous Cellular Membrane—Use of the Nitrate of Silver.—From a Clinical Lecture by Professor Elliotson.

I HAVE a case, Gentlemen, to speak to you about which is very interesting; it is that of George Hemmings, who was admitted the 4th of last month, with inflammation of the sub-cutaneous cellular tissue. He is about 40 years of age, of a sallow complexion, and has lived intemperately; he has been occasionally subject to attacks of bilious vomiting during the last two years. It appears from his statement that he caught cold last winter while under the influence of mercury, and that he has not been well since. A fortnight since, he was attacked with rigors, which were followed by heat, pain in the head, and thirst. The left side of his throat became sore, the right side of it was also shortly after affected. He observed in a few days that on the right side of the neck and upper portion of the chest, the skin was red, swollen, and very tender when pressure was made on it. He was bled twice for these symptoms, and leeches and a blister were applied to the left side of the chest, which was slightly indurated, but not redder than natural. These measures did not remove the symptoms, but, on the contrary, they continued to extend, spreading quickly over the shoulders, the inside of the arm, and fore-arm, so that motion was attended with much pain. When pressed on, the redness disappears, but immediately the pressure is removed, it returns. Pressure on the calves of the leg gives him pain, particularly on the left one; several indurated lines can be traced on them. There is pain in the popliteal space, on extending the knee joint, and tenderness of the epigastrium on pressure.

He is troubled with a slight cough, which is attended with expectoration of a frothy mucus. Respiration is sibilant over the whole chest, but more especially on the left side; he experiences pain on taking a deep inspiration. His pulse is 90, and rather full—he has considerable thirst, and his bowels are confined—urine scanty and high-coloured—the tongue covered with a yellow fur, in the middle clear, and moist round the edges—countenance anxious. Such is the report of the symptoms on his admission. I concluded at once that there the subcutaneous cellular tissue was inflamed. I ordered the shoulders, arms, and the right side of the neck, to be washed with a solution of the nitrate of silver, and ten grains of the pill hydrarg. to be taken every six hours. The caustic had the effect of stopping the extension of the inflammation. The tonsils, velum, and the adjacent mucous membrane became inflamed, for which he was ordered an opening draught and a gargle.

On the 7th he was much better, the neck was softer and less tender on pressure—the mercury affected the gums slightly.

Up to the 23d there was nothing remarkable occurred; he had occasionally slight rheumatic pains about the shoulders; for these he was blistered and relieved—a tonic mixture was afterwards ordered, and save a slight tenderness and hardness in the calves of the legs, with occasional rheumatic pains in the palm of the left hand, and ball of the thumb, he did well; and on the 19th was reported cured.

This case is interesting from the plan of treatment adopted; you may probably remember, that in one case, similar to the present, which we had a short time since in this hospital, that the nitrate of silver was applied, but it had not the effect of stopping the progress of the disease: the man died. On examination after death, the cellular tissue was found in a pulpy, pappy state; but not more so under the parts where the caustic had been applied, therefore that could not be said to have increased the disease. Besides, the gentleman who applied the remedy had done it improperly and partially, rubbing the skin with the caustic in the stick, not, as it should be, in solution. In the present instance, when properly applied, the effect has been decided and successful. The profession are indebted to Mr. Higginbottom for their acquaintance with the use of this medicine externally. It is unquestionably one of the greatest improvements in the modern history of medicine. Before the use of this medicine was known in erysipelas, cases of attacks of that disease in the head used to distress and annoy me. No matter what means were employed, bleeding, mercury, and cold, seemed equally uncertain in their operations; but, since the introduction of this medicine, I do not dread these cases as I used. I have

applied it very many times with the most decided success, and I can confidently recommend its employment. The case just related is a most decided proof of its utility. The man was of weak constitution, and bleeding could not have been resorted to: here was a fearful inflammation going on, and, but for this medicine, would probably have terminated fatally. I have used the nitrate of silver in other cases attended with discharges from the rectum, the urethra, and vagina, as an injection, in one-tenth of a grain in gonorrhœa, and one-fourth in leucorrhœa. It has also, certainly, great power taken internally in various nervous diseases, particularly hysteria and epilepsy.

—o—

MEDICAL BENEVOLENT INSTITUTION AT LIVERPOOL.

We have much pleasure in directing the attention of our readers to an account of the establishment of a Medical Benevolent Institution at Liverpool. The advantages of such establishments are extremely great to our brethren. Thus we have known an instance in the Benevolent Institution of Essex, in which a member paid one annual subscription of two guineas, for which his wife and family have now received 500*l*. We would strongly recommend our junior brethren to join the London Medical Benevolent Institution, from which they may derive great advantages. Each widow is allowed 35*l*. a year, and each child 12*l*., until the age of fourteen years, when it is apprenticed. We wish that similar institutions were in every city in the empire. The annual subscription is two guineas.

To the Members of the Medical Profession.

In directing your attention to the formation of the Provincial Medical Benevolent Society, the committee beg leave to offer a few remarks respecting its origin and objects.

The important rank in the medical world which the Provincial Medical and Surgical Association has now attained—the great number of members of which it consists—the benefits which have resulted from its anniversary meetings, not only in the advancement of science, but in the renewal of social intercourse, and the more general diffusion of friendship and kindness through all ranks of the profession in the provinces, and the facilities for considering and accomplishing any important and general object, which are afforded by the annual re-union of so many professional men, from all parts of the kingdom, have induced some members of the Association to conceive, that by its instrumentality the formation of a benevolent society, which might eventually comprise amongst its members the great majority of provincial practitioners, might

be the most readily and effectually accomplished. The outline of a plan having this object in view was submitted to the Association, by Dr. Baron, at the meeting held at Bristol, in 1833.

At the second meeting, held at Birmingham, in 1834, a committee was appointed to consider the practicability of carrying the design into effect, consisting of the following members:—Dr. Jeffreys, Liverpool; Mr. Wickenden, Birmingham; Mr. Wilson, Manchester; Dr. Baron, Cheltenham; Mr. Ransome, Manchester; Dr. Evans, Birmingham; Dr. Booth, Birmingham; Mr. Williams, Holywell. To whom were afterwards added—Dr. Jas. S. Bardsley, Manchester; Dr. Brandreth, Liverpool; Dr. Scott, Liverpool.

At the third anniversary, held in the Radcliffe Library, in Oxford, in July last, a very satisfactory report was presented to the Association, strongly recommending its adoption, and describing its objects and the principles upon which they proposed that it should be conducted. This recommendation was very favourably received, and unanimously adopted by the Association, and it was resolved—

“That the original committee be re-appointed, with unlimited power to form sub-committees in the several towns, so as to enable them to carry into effect their recommendation; and that they be requested to report their proceedings to the next anniversary meeting.

“That the following towns be nominated as fit places for the formation of committees, viz:—Cheltenham, Liverpool, Manchester, Birmingham, Oxford, Bristol, Bath, Reading, Worcester, Hereford, Warwick, Chichester, and Monmouth, and that Cheltenham be fixed upon as the town where the central committee shall be formed.

“That subscriptions be forthwith entered into, and that Dr. Wm. Conolly, of Cheltenham, be appointed treasurer *pro tempore*.”

The following gentlemen have been appointed a committee for Liverpool: Dr. Jeffreys, Dr. Brandreth, Dr. Scott, Mr. Bickersteth, and Mr. Dawson.

The committee, therefore, earnestly trust, that it will receive the cordial support of the profession at large, and that each individual member will endeavour to promote its success in his immediate sphere; and it is hoped, that many benevolent individuals, unconnected with the medical profession, but grateful for the blessings which they have derived from the exercise of medical skill, as well as from motives of general philanthropy, will materially assist in its advancement, so that in no long time it will be sufficiently matured, not only to accomplish the primary object of its establishment, but to afford, in many instances, permanent assistance, to rescue from poverty, in all cases,

the aged and infirm—to diffuse peace and comfort through their declining years, and illuminate, with fraternal sympathy, their dark and cheerless passage to the grave.

The following contributions have been received, and the Liverpool committee will be happy to receive donations and subscriptions, and the names of those who may be willing to become contributors.

Donations.—Dr. Kidd, Oxford, 20*l.*; Dr. Currick, Bristol, 20*l.*; Dr. John Johnstone, Birmingham, 20*l.*; Dr. Baron, Cheltenham, 20*l.*; Dr. Hastings, Worcester, 2*l.* 2*s.*; Mr. Seager, Cheltenham, 2*l.* 2*s.*; Dr. W. Conolly, ditto, 2*l.* 2*s.*; Dr. Barlow, Bath, 2*l.* 2*s.*; Dr. Jeffreys, Liverpool, 2*l.* 2*s.*; Mr. Griffith, Hereford, 2*l.* 2*s.*; Mr. T. Griffith, Wrexham, 2*l.* 2*s.*; Mr. Hitchings, Oxford, 2*l.* 2*s.*; Dr. Scott, Liverpool, 2*l.* 2*s.*; Dr. Bleck Lye, Hereford, 2*l.* 2*s.*; Mr. Paxton, 1*l.* 1*s.*; Mr. W. Davis, 1*l.* 1*s.*; Mr. Brooks, 1*l.* 1*s.*

INSURANCE OFFICE QUERIES.

To the Editor of the London Medical and Surgical Journal.

SIR—You deserve well of your profession and the community at large, for your clear and ardent elucidations of the mean, dishonest, and degrading dispensary system. There is another department to which I have to call your attention, by which medical men suffer, and that is the insurance office department, who transmit their queries to professional men, and, to answer which conscientiously, requires time, skill, and attention; but no fee, or assurance of such, attends these applications (inducing the belief that there is no want of modest assurance at these offices), which invariably ought to be the case. When an individual presents himself for insurance, the office to which he applies should call on him to deposit two guineas, to accompany the said queries, which would give the application a decided claim to attention. I am, &c.

HONESTUS.

Sept. 3rd, 1835.

LITERARY NOTICE.

In the press and shortly will be published, an Interlinear Translation of the Second Book of Celsus, with the Order and Numbers of most of the Words attached. By Gurney Turner, Esq.

—o— CORRESPONDENTS.

Inquirer is right. The various articles on dreams and sleep, which have lately appeared in this Journal, are from an unpublished Lecture on “The Philosophy of Dreams and Spectral Illusions,” delivered by Mr. J. F. Clarke, at the City of London Literary Institution.

All communications and books for review are to be addressed (post paid) to Dr. Ryan, 4, Great Queen Street, St. James's Park, Westminster; or to G. Henderson, 2, Old Bailey, Ludgate Hill.

LECTURES

ON THE

INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXIX.

Hypotheses concerning the Proximate Cause of Muscular Motion.

I.—The first opinion, that the change in the figure of a muscle, during its contraction, is effected by an influx into the vesicles of which its ultimate fibres were supposed to consist, of nervous energy, which was believed to be capable of swelling them in one direction, while it shortens them in another, is the most ancient one upon the subject, and it has been adopted by some physiologists of our own times (*a*). The latter have attempted to support it, not only by trying to demonstrate the really vesicular structure of the ultimate fibres of the muscles, and by laborious calculations of the necessary effects of their inflation, but by the observation, that the contractions of a muscle always take place in a vibratory manner; (*b*) and this they say may be presumed to correspond with the intermitting jets into them of the nervous energy, which is by many of the modern advocates of this doctrine identified with galvanism. They omit, however, all the anatomical and mathematical part of the question, the former of which is pretty certainly erroneous, and the latter equally certainly inapplicable; the circumstance of the vibratory character of vascular contraction may surely be, with as much likelihood, ascribed to numerous other necessary conditions of this contraction, as to successive jets into the muscles of a supposed substance of the existence of which there is neither proof nor probability. The only stimuli to muscular contractions, which are conducted by nerves, appear to be sympathy and passion, or instinct, on the one hand, and volition on the other, and that these are not, any more than any other such stimuli, material, has been already abundantly insisted upon. They may stimulate the muscles to undergo the change in question, but they do not immediately effect that change by pouring any thing into them. Besides, how are we to conceive that heat, and the numerous other direct stimuli to irritability, operate in exciting muscular contraction, if it be by the influx into the muscles of nervous energy that it is effected; and how is it to be explained upon this principle, that muscles continue to contract, upon the application to them of these direct stimuli, during sleep or coma, and even after apparent death, as well as after all their principal nerves have been tied, after the brain has been removed, or after the muscle itself has been separated from the body, when, of course, every avenue by which a supply of the supposed nervous energy can be presumed to be furnished must have been cut off?

II.—The second influx which has been brought forward in explanation of the proximate cause of the contraction of muscles, is that of blood, which is presumed to pucker up the alternate muscular filaments by the turgescence, which it occasions in the contiguous blood-vessels (*c*). The principal arguments in favour of this hypothesis are, in addition

(*a*) This was the surmise of Galen; and it has been supported by Descartes, F. Sylvius, Borelli, Hoffmann, Stuart, and others, in modern times, as well as by many of those physiologists in our own day, who choose to identify this imaginary substantial nervous energy with galvanism.

(*b*) Roget (*De perpetua Fib. Musc. palpitazione*, 1760); Wollaston (*Phil. Trans.* 1810); Laennec (*De l'Auscultation Médiate*, 1819), &c.

(*c*) This hypothesis has been maintained principally by Swammerdam, Baglivi, Cowper, Fowler, Ward, and Prochaska.

to the established fact, the force of the contractions of muscles in all animals, at all ages, and under every variety of circumstances, is in the direct ratio of their vascularity; in the first place, that the force of such contractions, on the application of any stimulus, is found to be more increased by increasing the quantity of the blood sent in a given time to the muscles, so that these supposed jets become more powerful (a); secondly, that the celerity of these contractions is diminished by diminishing the rapidity of the circulation through the muscles, as is supposed to be proved by the peculiar arrangement of the arteries going to the extremities of the tardigrade animals, as the sloths and lorics, which is such, it is believed, as must retard the flow of the blood, and may thus, by diminishing the rapidity of the jets into the muscles, explain the sluggishness of their motions (b); and thirdly, that these contractions are altogether prevented, after a time, by tying the arteries going to a limb, while obstructing the larger nerves is, as has been already explained, comparatively nugatory in this way (c)—a circumstance which can be accounted for, it is imagined, only on the presumption that the former operation obviates, while the latter does not, the jets of blood into the muscles in which the proximate cause of muscular motion is conceived to consist. Against all the arguments, however, supposing the facts to be as is stated, it might perhaps be sufficient to say that the blood being one of the most powerful stimuli to the contractility of muscles, it might easily be supposed that an increase, a diminution, or an exclusion of this fluid, would produce a corresponding effect on their contractions, without the inference that it was upon any direct influx of blood into the muscles that these contractions immediately depended. But against the second and third of these arguments it may be alleged further, that the one rests on the presumption of facts which have never been made out, and that the other admits of an explanation even more satisfactory than that founded upon an exclusion of a natural stimulus. For, with respect to the former, it remains to be proved, first, that the peculiar distribution of the large arteries of the limbs of tardigrade animals is such as to retard the circulation of the blood through them; secondly, that the motions of these animals are really, under equally favourable circumstances, slower than those of others; and thirdly, that, if both these facts are as alleged, the one is the cause of the other. The peculiarity alluded to consists in this, that the humeral and iliac arteries of some of the bradypoda are found, like the internal carotid arteries of some browsing animals, to be very much subdivided in their course; and these subdivisions will unquestionably, by increasing the collective calibre of the passage for the blood, retard its course in *this particular part*; but if these arteries are afterwards re-united before they are distributed into the branches which supply the muscles, it is manifest that the original celerity will be restored. Again, although the sloth and other reputedly tardigrade animals, when crawling along a flat surface, in which case their long claws are an incumbrance to them, and every feature of their structure is ill adapted to a rapid progress, move sluggishly, and with difficulty, is such their motion when hanging by their claws from the lower part of the branches of trees agitated by a storm, and under circumstances in which many animals, the fleetness of which on even ground is so superior, could not move at all? Further, it seems to be absurd to connect the idea of essential celerity or tardiness of muscular contractions with any distribution of the arteries; as if the motions of the same animal were not quick or slow, according to many circumstances, while the distribution of its arteries remains unchanged; and as if the course of these arteries were not often materially altered, without entailing upon an animal any general peculiarity in these respects—without converting, as it has been idly attempted to do by these means, the sloth into the spaniel, or the spaniel into the sloth (d).

(a) This fact was observed by Fowler, while engaged in exciting the contractions of the muscles of a frog by electricity. (*On Animal Electricity*, 1798).

(b) Sir Anthony Carlisle (*Croonian Lectures*, 1800-1805).

(c) Stenon, Cowper, Boerhaave, Brunn, Brodie, &c.

(d) It is astonishing that persons who are aware that one artery after another, as well in the human body as in that of brutes, has been tied, and every possible variation in the character of these vessels as ministering to the several organs, has been thus produced, without any, or with very inconsiderable effects on the functions of these organs, can still continue to vapour about the subdivisions, angles, degrees of tortuosity, and so forth, of particular arteries, as influencing

in any remarkable degree the functions of the parts which they respectively supply. The doctrine is not yet quite obsolete that, as the apparent inactivity of the sloth depends upon the subdivisions of the main arteries of its limbs, so the usually greater energy of the motions of the right arm of man, than of the left, arises from the greater concentration of the artery by which it is primarily supplied, without regard to the fact that the right leg and whole right side of the body are in general in the same degree more energetic than the left, as the right arm. There are many, too, who still cling to the belief that an artery which, like the renal, arises from the aorta at a right angle, or one which, like the internal carotid, proceeds in a tortuous manner to the place of its destination, receives less blood or conveys

Every thing relating to this argument, therefore, appears to be objectionable; and, with respect to the last on the same side, that tying the arteries of a limb after some time quite destroys the contractility of its muscles, this may be easily explained, as elsewhere stated, without the presumption that it is in any direct influx of blood that the proximate cause of muscular contraction consists. For, not to recur to the want of the proper supply to the muscles, in this case, of one of their most essential stimuli, we must remember that it is by the blood that the nutrition of the limb is maintained, that its ganglionic nervous tissue ceases in this case to be renewed, in proportion as it is exhausted, and that there is consequently after a time a cessation of irritability—a necessary condition of muscular contraction. No thing of this kind takes place when only the larger nerves of a limb are divided, which sufficiently explains why the retention of muscular contractility in the part is quite compatible with this operation (a). — And that is by impeding nutrition, and not by obviating any presumed jets of blood, as immediately instrumental to the contraction of muscles that this tying of the arteries operates, is rendered further probable by the fact that if the veins, as well as the arteries, are included in the ligature, the contractility of the part is preserved for a longer period than if the arteries alone are tied (b). In this case it is very easily understood, that from the blood being retained in the capillary tissue—the immediate instrument of nutrition—much longer than in the other, this process will continue for a longer time uninterrupted; but it is much less conceivable how any retention of blood in this tissue should be favourable to muscular contraction in the manner above supposed. It may be remarked further, that the retention of their irritability by the several organs after apparent death, is found to be, *ceteris paribus*, proportioned to the quantity of blood which they contain—a fact which is more easily reconcilable with the presumption that this blood still ministers in some degree to nutrition, than that it effects—now that the larger arteries are all for the most part empty—any such jets as have been imagined. But, besides these objections tending to neutralize the several arguments in favour of the hypothesis in question, it may be alleged as positive evidence against it, that, supposing the blood to reach the muscle in action from the contiguous parts, it is quite inapplicable, like the doctrine of an influx of nervous energy, to explain the contractions of a muscle, on the application to it of the requisite stimulus, after its removal from the body, when every such supply of blood has been intercepted; and that it is quite inconsistent with the fact that the bulk of muscles, during their contractions, appears to be unenlarged; and whether this be the presumption, or whether it be supposed that the blood merely shifts from one part of the muscle to another, it is quite irreconcilable with any of the generally acknowledged powers of the circulation. It may be urged, indeed, that, conceding the independent action of the arteries, large and small, we have a power quite competent to produce the jets in question, whencesoever the blood may come; but allowing the greatest possible degree of latitude to this presumed independent action of the arteries—an action, which in the case of the larger arteries, is pretty certainly altogether imaginary—we must still, if this hypothesis be admitted, come to a point where general authority seems to desert us. For it must not be forgotten, that the independent action of the larger arteries, if any such exist, as well as that of the parenchymatous tissue, itself consists in muscular contraction, and whence can their coats be presumed to get the necessary jets of blood? If we say, in the former case, by their *vararum*, we still imply the muscular contraction of the latter; so that we are driven at last to the presumption that the blood, in the process of effecting muscular contraction, moves spontaneously—a presumption, certainly, quite inconsistent with the best established doctrines on the subject.

III.—But if the muscular fibre acquire nothing new during its contraction, in the way either of nervous energy or of blood, by what changes, chemical or mechanical, in its substance, is this contraction effected? It is hardly necessary to shew that it is not, as was at

it with less impulse than it would have done under different circumstances. It is quite time that all this trash, irreconcilable as it is with reason, and inconsistent as it is with recently established facts, should be abandoned.

(a) Dr. Elliotson attributes the “palsy,” which results from this operation, principally to the want of nourishment of the motiferous nerves, so that they can no longer act as vehicles of the accustomed stimulus. (Trans. of Blumenbach, Instit. of Physiol. 1820). But it is not merely “palsy”—which consists only in a defective

conveyance of such indirect stimulus—but a total want of capability on the part of the muscle to obey any stimulus whatever, indirect or direct, which is the consequence of the operation in question—not a loss of the power to excite, but of the faculty of being excited. If its effects were on the motiferous, and not on the ganglionic nerves, how could it happen that dividing the former does not produce it? It does produce palsy, but that is a very different affair.

(b) W. F. Edwards (*De l'Influence des agents Physiques*, &c. 1824), Dr. J. P. Kay (Edinb. Med. and Surg. Journ. 1828).

one time supposed (*a*), by the expansion of the air which the muscle contained, like that which occurs in a shrunk bladder upon the exhaustion of the circumambient atmosphere, that this takes place; and the doctrine that it depends upon a kind of effervescence or explosion, arising, as some have imagined; (*b*), from the combination of certain inflammable gases or other matters contained in the muscles with the oxygen or other matters constantly brought to them with the blood, which combination is effected by the nervous energy—afterwards identified with galvanism—conveyed to them at the requisite periods by the nerves, cannot surely require any serious refutation. It may be allowed, like the two former, to sink quietly into the vault of all the Capulets, in company with all the rest of that chemical mummery which was at one time unfortunately so fashionable in physiology.

IV.—Nor is the hypothesis that muscular contraction depends upon the coagulation of the supposed fibrin of the muscle, dependent upon some change in the proportion of its elements (*c*), at all more happy, or more worthy of a lengthened examination. It has been already weighed in the balance incidentally, and found wanting. Such coagulation of their fibrin is pretty certainly the cause of the rigidity of the muscles after death; but how different a process this is from their contraction during life, is clear from the fact that the former does not take place while irritability is still energetic—in other words, immediately after death—but only when this is already exhausted—in other words, from two to eighteen hours afterwards—and from its occurring as remarkably—perhaps even more remarkably, like all dead processes—in weak subjects than in strong ones. If this hypothesis respecting the proximate cause of the contraction of muscles were true, it would cease to be a question whether the stiffness of the joints after death depended, in any given case, on the ordinary post mortem rigidity, or on spasmodic contraction—a question sometimes of very great interest—since it is obvious that no distinction would exist between them. But the circumstances of the two are in every respect different, and their proximate causes must therefore be presumed to be so too. Living muscles contain, in all probability, no fibrin; and it is fortunate for us that they do not, since if they did, it must—for it would not otherwise be fibrin—coagulate, and such coagulation, so far from effecting, would be incompatible with muscular contraction.

V.—There remain only the doctrines of some mechanical changes in the muscles to explain their contraction; and, according to some physiologists, it consists merely in an increased degree of that attraction by which the particles of matter of every kind are kept in contact (*d*). This explanation, however, unless it be so far modified as to allow that the increased attraction takes place in one direction only, and that in proportion as it is diminished in another, is quite inconsistent with the fact that the volume of a muscle is not altered during its contraction. But such a modification has been attempted, and the whole thing has been referred to the globules, of which the ultimate fibres of muscles are supposed to consist, which are presumed to become changed, by some peculiarity in this attraction of cohesion, either in their figure, or in their relations to each other in this process. It has been imagined, that whereas while the muscles are in a state of rest, or contracted only to a degree which we consider as their rest, these globules are rather elongated in the direction of the fibres of the muscle than spherical, and the amorphous matter between them is copious, so when they are in action the former are brought each to the figure not only of a sphere, but even of a compressed spheroid, and the previously interposed amorphous matter is squeezed out from between them (*e*). The principal objection to this doctrine, to say nothing of its offering no explanation of this peculiarity in the operation of the ordinary cohesive attraction, is that it is a mere hypothesis, without any substantial evidence in its favour. It is perhaps adequate to explain the phenomena in question, but it is time enough to inquire, according to the admirable rule of Newton, already spoken of, whether any doctrine "*phænomenis explicandis sufficiat*," when we have adduced some reasons for believing that "*vera est*;" and that this doctrine cannot possibly be so, if the objections to the globular structure of the muscles already alluded to be substantiated, is obvious.

LECTURE XIV.

Croup.

THIS disease made a great noise in France, from the concours on the subject ordered by Napoleon whilst he was yet on the throne. At that time his child was of an age when croup was to be feared, and he wished to stimulate the zeal of the profession by a prize. The conclusion from the first researches thus induced was, that the croup was an inflammation—an important point ascertained: that the false membrane was owing to this inflammation: that the danger depended on the concreted mucosities which gradually narrowed the glottis: yet that cases occurred in which patients died asphyxiated without any appearance of false membranes. They were not satisfied with the injection, swelling, and concretions, as explanatory of the suffocation; spasm was considered as the determining cause, although it is only the consequence of the inflammation; in fact, when the larynx is inflamed and its mucous membrane swelled, it is impossible that there should not be a violent constriction of its muscles, which together with the inflammation contributes to the narrowing. This question is not one for the larynx alone, but for many other organs, so simple and so evident is the answer to it; the velum palati, the cardiac, and pyloric orifices, and body of the stomach, the urinary bladder, &c., are all liable to become spasmodic when they are inflamed, and still more likely is the larynx to be so when in a state of phlegmasia. This spasm is stronger or weaker according to the nervous habit of the patient; this fact should be noted, but is no ground for making out a nervous croup, just as they have made an inflammatory croup from inflammation, or a mucous one from the mucous secretion—distinctions that scent of the old things of the four temperaments: why did they not make a melancholic croup?

These ideas prevailed, and practitioners represented the inflammation as primitive in the larynx, with divers forms and determinate limits, when M. Bretonneau's work appeared, a valuable work in so far as the author relates what he has seen, and as he often avows things that do not speak in favour of his own views, adding thus the merit of candour to it. But he has neglected several important points and given imperfect explanations. He does not consider croup to be a primary and isolated disease, but makes it dependant on a general modification of the upper mucous membranes, called diphtheritis, never commencing in the larynx, and of which croup is a section, or, if you choose, a consequence. To the support

of this opinion he brings facts on the interpretation of which medical men vary. It has been objected that what he looks upon as the preludes of croup is only the beginning of a gastro-enteritis, and that in such case his remedies are uncertain; that when they succeed it is because the disease has commenced without preludes in the velum palati; that when they do not succeed it is because he has neglected to combat the visceral inflammation that preceded that of the larynx.

The question therefore is, whether a primary croup does exist; and to this we are bound to answer in the affirmative, for it is shewn to be so by the modern treatises of Bretonneau, Bland, Emangard, and others. The essay of the latter author more particularly is filled with numerous facts that certify a primary croup in the larynx, and cures obtained by crushing the inflammation in its onset. The same was proved in the majority of the works published for the Napoleon prize. This does not however prevent the possibility of the mucous and membraniform secretion of the larynx forming part of a general tendency to that secretion throughout the extent of the upper mucous membrane, and of its appearing in the organ of voice after occupying other organs. Both primary and consecutive croup may be found; I repeat this in precise terms, lest it should be wilfully perverted and an opinion attributed to me, as is frequently done, which is none of mine: *for my adversaries are most skilful in refuting what I never said, and even what I myself have refuted!* I do not then maintain that no such thing as M. Bretonneau's diphtheritis exists, but I do maintain that there are primary croups. Had that author his eyes blinded on the matter of croup? not he: only when he arrested it he said it was only a cold; thus it is that our adversaries reason. You shew them an incipient phlegmasia of the larynx, and you crush it—they tell you you have only cured a simple cold. The same objection in the case of gastro-enteritis: suppose you have twenty of them under treatment and you arrest eighteen—the two that persist are the only *essential fevers* among them, say our adversaries. Both objections are equally false: every disease that is not arrested might have gone on and become serious or even mortal; be convinced of this truth and you will be physiological physicians.

Take example from M. Emangard in the examination of croup. When he went to practise at L'Aigle, the opinion held there from time immemorial was, that every one attacked with croup must necessarily fall a victim to it. He boldly and promptly combated it, with antiphlogistics first, and then with emetics, made a revolution in opinion in the town, and now the converse is the popular bye-word. This fact is sufficiently important to merit attention, if not from a feeling of justice, at least from that of personal interest; but justice does guide you

and tells you that every man has an equal right to revolve, weigh, and judge, with all possible sincerity, the assertions that are made; and it does not content an intelligent audience, as you are, to hear people saying that this author or professor is enchained by one idea, because he has the courage to think differently from others. You should demand proofs and demonstrations, and therefore it is that you cannot fail to yield serious attention to M. Emangard's authentic and irrefutable fact: remember this is a question of conscience as much as reason. Being on the jury last year, I gave up twenty-four and thirty-six successive hours to a small police affair, that was certainly nothing in comparison with croup, which is a capital question, serious as capital punishment itself—indeed more so, since it perils the lives of innocent beings; and one which you are often called upon alone to decide upon. Again I say that croup may be primary or consecutive in the larynx, confined to that organ or extending to others, but most frequently consecutive; when they have made me say otherwise, sophistry has been employed, and my words have been perverted. Trace we now the history of this formidable disease.

Cold is the most powerful cause of croup; you may tell me that marshy emanations assist in its production: I think that most frequently they have nothing to do with primary croup, but that united to moist cold, they influence the production of croup complicated with extensive phlegmasiæ of the mucous membranes, such as diphtheritis. Cold acts more powerfully when quickly following on heat; an easterly wind is a very fertile cause of it in young, lymphatic subjects, who are, generally speaking, more subject to it, though the robust are by no means exempt. It most commonly occurs previous to puberty, when the constitution is more lymphatic, the larynx narrower, and the entrance and exit of air less easy. Its onset is made in several forms; one slow, commencing with a simple cold, hoarseness, slight cough, mucous expectoration, during several days, after which the child exhibits the characteristic symptoms of croup; the other sudden, in which the child is all at once seized with the characteristic croupy symptoms, which are a cough called croupy, or asnerine by some others, from its resembling the scream of an enraged goose; a cough that is stridulous, as if it passed through a brazen tube, and accompanied with a râle during inspiration, that is painful to hear, and which when once heard can never be forgotten. As the disease proceeds the patient becomes anxious, from the difficult respiration; he stretches his neck, stiffens it, throws his head backward, and by an instinctive movement applies his hand to the larynx, as if to facilitate the introduction of air: it is the same kind of instinct that leads animals to lick the part that pains them. The noise of mucosities moved about by the cough

is heard, and we may even sometimes feel with the hand, and still better with the stethoscope, the movement upwards and downwards of the false membranes. If any uncertainty remains it soon disappears before the anxiety and terror that are depicted in the attitudes of the patient, his swollen face and livid complexion; further light is thrown on the point, if portions of false membrane are expectorated by the cough.

Regarding the secondary phenomena, first come those of propagation of the irritation, which may reach the bronchi (and with the stethoscope the râle may be heard), and may also extend to the pharynx and the velum palati, producing false membranes there. These phenomena of propagation are possible but not constant. Those of dissemination are first, fever, which is not slow and gentle at the commencement, and does not appear until the disturbance has extended into the system, and then is difficult respiration. The frequency and force of the pulse, as well as the spasm and agitation, depend on the individual temperament and susceptibility. Were I to trace a picture of these phenomena to you, it should be taken from two or three nearly similar individuals, and would probably only resemble others by chance, so that you might not perhaps meet a single other croup that resembled it. Nothing is more insidious than those picturesque descriptions of a disease, that are made by inspiration as poetical pieces are, and which might be given in verse as well as prose; they no more represent the object the authors have in view than does a general likeness of the human species resemble the face of one individual. You should fix upon the principal phenomena alone, around which the others are grouped. To give you an idea of this, I would say that if the head becomes affected, then is redness of the countenance, agitation, delirium: if the irritation takes possession of the stomach, then is heat and epigastric sensibility, nausea, red, dry, fuliginous tongue, &c.; if it extends to the lungs the respiration is perturbed, laborious, anxious, with painful convulsive cough, expression of terror, &c. But all this assemblage has no length of time for production: as soon as the false membrane forms the patient is already nearly strangled: these phenomena do not last more than a moment, and death rapidly follows them: the principal attention should therefore be given to the respiratory tube when there is supersecrection.

In our time the progress of croup is rarely allowed without some attempt to interrupt it; in times past it was permitted to go on, and the patients almost invariably were suffocated in a state of prostration, with engorgements of the head, chest, and abdomen, with extensive inflammations and more or less putrescency. Even now-a-days cases are met with where the disease is not combatted, and the cure is left to nature, who effects it by virtue

of a law which it is well to ascertain in order to give her credit for it, and not exaggerate the potency of our means. According to this law, whenever a concretion takes place in the course of a mucous phlegmasia, there is a tendency to an exudation beneath it which detaches it. If this concretion is in the nose, we blow it; if in the throat or larynx we spit or expectorate. It is possible that when croup occurs in strong, well constituted adults with a large glottis, the cough may cause the expectoration of two or more cylindrical false membranes, and the patient get round: whilst children, whose larynx is narrower, suffocate before the loosening and expectoration can be effected. When patients thus expectorate false membranes, they are relieved, the fever diminishes, the respiration becomes free, they even sometimes ask for food, if there be no cerebral congestion or visceral inflammation: but on the following day new membranes may form and the mischief be renewed, which shews that there is no certainty in the progress and issue of a croup that is not treated. Every thing is subordinate to individual constitution and divers involuntary and unforeseen circumstances; sometimes the false membranes are produced in the space of five or six hours, and threaten suffocation, then are driven off by efforts of coughing, form again, are again expelled, and the patients die not. This scarcely happens in children, on account of the narrowness of the air passages: there are however instances of it. I have seen chronic croup in adults, who expectorated false membranes at distances of two or three months.

In summing up what refers to this part of the history of croup, we observe: 1. Death by general dissemination of the inflammation, simultaneous cerebral and pulmonary congestion, suffocation, particularly if the patients have been stimulated. 2. Death by simple suffocation, without congestion of head or chest. 3. Prolongation and sometimes cure of the disease by expectoration of false membranes. 4. Diminution of fever and irritative symptoms after such expectoration, return of fever and of those symptoms when the membranes are reproduced. 5. Possibility of prolongation to the chronic state in adults, infrequency of this prolongation in children.

When we are enabled to inspect the bodies of either after death, we behold multiplied forms of false membranes, hard, dense, coriaceous, half loosened, floating, or adherent, formed of several superimposed layers, the external dried by the heat and air of respiration, and the others less and less coherent, as we approach the surface whence they were secreted, some denser, some more diffuent. When they have thus deeply inlaid the respiratory surface, the suffocation has been sudden, almost electric. During the last seventeen years, I have met three or four cases of such

sudden death in adults. In the autopsy we drew from the mouth, larynx and bronchi, concretions that exactly resembled a polypous tree, whose branches were certainly hollow but left no room for the entrance of air into the lungs. Moreover, no air could be of use in oxygenating the blood when such concretions intervened between it and the sanguineous capillaries. The inflammation subjacent to the false membranes is not always readily traceable in children: more generally there is a slight redness, rather than a deep colouring, of the mucous membrane: this depends on the quantity of blood that has been lost, or the rapidity of the death, or the more or less inflammatory or catarrhal shade of the disease, &c. If it has existed in the shape of catarrh, and the child has been freely bled, there may be scarcely any redness; take care, however, how you thence conclude, as did some of the candidates for Napoleon's prize, that the disease is not inflammatory.

The secondary cadaveric phenomena are cerebral or pulmonary congestion, or even decided inflammation of the brain or lungs, especially in those that have not been bled, but rarely any appearance of pleurisy or gastritis.

To establish the prognosis you must rest on two symptoms, the cerebral or pulmonary congestion, and the imminence of suffocation. A child or adult suddenly seized with laryngitis may have so violent a pulmonary congestion or sudden cerebral apoplexy, as to perish before the stoppage of the air passage has taken place; this is rare, but not impossible. Most frequently the danger arises from suffocation, and the prognosis is to be drawn from the difficulty of respiration; when the face is injected and turns purple, with streaming eyes, stretched and swollen throat, the gestures evidencing an ungratified desire for air, when the upper muscles of the chest, that are fixed to the clavicle and sternum are forced to assist the ordinary respiratory muscles, and the respiration is what is called sublime, the danger is great, but becomes immediate when the pulse is small, thready, extinct, and asphyxia commences: death is then for the most part inevitable. Though false membranes have been rejected, we are not hastily to conclude that the disease is over, for they may be reproduced. Cases even occur in which the croup is intermittent, as all other irritations may be, so difficult is it to isolate from any given disease phenomena that are owing to some other.

Lastly, in an advanced stage, when the patient is no longer threatened with suffocation, secondary phlegmasiæ come on. The inflammation of the larynx having ceased, and the cough being no longer any thing more than catarrhal, he may be threatened with death either by gastritis, or pneumonia, or pleuritis; the danger, of course, will be pro-

portioned to the intensity and duration of these inflammations.

The treatment should, first of all, be antiphlogistic; such was the general opinion when M. Bretonneau began to preach the harmfulness of such a method, and to cry up topical means, such as alum, lunar caustic, and hydrochloric acid. But the conviction of this our worthy confrere only rests on an imperfect notion of the disease, and on the supposition that it always commences in the tonsils and velum palati. His principal indication is the employment of topical means to put a stop to the inflammation in those parts, and to prevent its propagation into the larynx, bearing in mind those numerous cases in which it commences in the latter organ, and where these means are not applicable. I am far from rejecting them, or denying their advantages when the disease really takes its start from parts that are accessible by those remedies; but as other observers, not less worthy of credit than M. Bretonneau, and among whom I venture to place myself, maintain that they have, by early local bleedings, undermined the inflammation that generates these false membranes, wherever it might be placed, I am of opinion that such bleedings ought to form the main curative means. General bleeding may also be useful to full-blooded adults, whose respiration and circulation are impeded, and who are subject to congestions in the great viscera. Except in this case, which also requires the after application of leeches, these are the surest remedy when used immediately and boldly on the larynx; they make the inflammatory movement sink, and in 24 or 36 hours the difficulty of respiration has disappeared, and the cough become simply catarrhal. For the rest, chemistry and physiology tell us that the concretion of the mucous, and the formation of false membranes, are owing to the excess of the inflammation and the heat it develops in the parts, conjointly with the respiration; diminish this heat, and its main cause, the inflammation, and the coagulation of the mucus immediately ceases. Together with leeches, you must be active with emollient applications, demulcent fluids, strict diet, revulsives, as blisters, pediluvia, and sinapisms. Should false membranes form, notwithstanding these means, or because they have been applied at too late a period, as they do not possess the power of doing away with them, you must endeavour to imitate nature by producing a mucous fluid beneath them, and then expelling them by coughing efforts, or by vomiting. Emollient vapours should be inspired, which render the false membranes more readily detached, while they at the same time diminish the heat of the throat and lungs, and provoke emesis; for it is her own mechanism that nature most frequently employs in expelling the mucous products of the croup and whooping-cough. It is true the tartar emetic you employ may pro-

duce a smart irritation of the stomach, and even a gastritis; but this should not deter you from its use, for you will have time enough to treat the latter; whereas croup admits of no delay; besides, the gastritis is not intense if sufficient bleeding have been practised. In calomel also you possess an active means of provoking mucous secretions, and though many practitioners pass it by or reject it, because it excites salivation and produces phlegmasiæ that spread to the mouth and add to the inflammation of the croup, it is not to be despised. After bold antiphlogistic treatment has been practised, calomel may be administered in the dose of a grain every hour or two, until it produces evacuations; when the cough is no longer croupy, it should be given up. If, by its use, an enteritis has been produced, just as the emetics produced a gastritis, it is to be treated by the usual means.

When it has become too late to withdraw the false membranes by means of inhalation and emetics—when the patient is scarcely breathing at all—when his pulse is extinct, and he is close upon death, tracheotomy is the only resource by which, according to M. Bretonneau, the false membranes may be extracted as they are formed, until, as sometimes happens, the tendency of nature to their formation is overcome. His treatise on diphtheritis contains a very remarkable instance of success thus attained. I could cite another, related by my son, Casimir Broussais, in the *Annales de la Médecine Physilogique*, vol. xv. But the most extraordinary successful instance is that by M. Scoutetten of Metz, on his own child, only a few months old. The suffocation had been so rapid, that in a few minutes the child was asphyxiated. The father had called several of his confreres to his aid, who declared the child to be dead. "Yet," said he, "suppose I operate. I do not hold life to be an abstract being, but matter that needs to be stimulated. I will extract the false membranes, and inflate the lungs—there is nothing to obstruct me—the child moves not—I shall perform the operation with coolness." He did operate; and after an hour and three quarters of uninterrupted efforts, a first sign of life appeared, and the child was saved, and is at this day well. I know of no fact to be compared to this.

Thus far I have treated of the inflammations of the exterior of the body that are accessible to our senses. In the next lecture we will commence our initiation into the mystery of visceral phlegmasiæ.

Dispensary, Gerrard Street, Soho:*

Session 1834-35.

LECTURE XLVIII

Pathology of Intestinal Worms.—It is impossible, in the present state of science, to determine the pathological condition of the intestinal canal, which gives rise to the origin of worms. It would be most important to determine this condition, as it would afford correct indications of treatment. It has been repeatedly observed that worms are found in the bowels of persons in perfect health, who were destroyed by some accidental disease. They have also been found in dogs that were killed in apparent health. They were detected by Andral in all states of the intestinal mucous membrane, red or pale, dry or covered with mucus. He informs us, however, that they were surrounded with mucus, under which the surface of the mucous membrane was red, but this was evidently the result of irritation, and must be considered the effect, but not the cause. Moreover, they have been found in every pathological condition of the mucous membrane, and even when it was in a healthful condition. According to this statement (and it cannot be questioned), the disciples of Broussais are in error, when they maintain that worms are not present unless in acute or chronic inflammation of the gastro-intestinal mucous membrane. The truth is, that we do not know the cause or origin of intestinal worms, and consequently we cannot prevent their formation. Is it only after the expulsion of worms that we are warranted in suspecting their presence in the bowels. The diagnosis is difficult; as their symptoms are equivocal, varied, are often present in other diseases, and are not to be depended on.

Symptoms of Worms.—There are no symptoms by which we can recognise the presence of worms in the bowels, except the rejection of them by vomiting or purging. All other signs of them are referable to gastro-intestinal irritation and its sympathetic relations.

Before we can understand or explain why irritation or disease in any organ of the body can derange and disorder the whole economy, we must know the anatomy of the body, which teaches us the continued nervous connexion between all parts, which accounts for their sympathies in health and in

disease. The anatomist experiences no difficulty whatever in understanding the structure and function of every organ, and the sympathy of organs in a healthful or diseased condition. This knowledge enables him to unravel the most complicated and multiform symptoms, to discover the primary seat of disease, and all the morbid phenomena connected with it. This can never be understood by private individuals. They cannot comprehend why pain or injury on a finger, toe, or any part of the body, may cause loss of appetite, loss of sleep, deranged vision, taste, smell, touch, hearing, or even tetanus. Thus they are astonished that the irritation of worms in the bowels can derange the appetite, irritate the mucous lining of the nostrils and lips, which is continuous with that of the stomach and intestines, cause itching of the nose or lips, or at the rectum, the opposite extremity of the digestive tube, induce bad health, paleness or yellowness of the countenance, languor, debility, irritation of the mucous lining of the generative organs, giving rise to yellow and purulent discharges, which have been too often ascribed to venereal contamination or attempts at violation, as already stated.

In all these symptoms the physiologist recognises the existence of an irritation, but he cannot determine its exact position without proper inquiry. He knows that irritation in any one part or organ of the body may cause the train of symptoms now described.

In addition to the symptoms already mentioned, those affected with worms, whether children or adults, have deranged appetite, diminished or voracious, foul breath, itching of the nose or anus, pale, sallow complexion, headach, nausea, hiccough, griping, diarrhoea, or constipation. The general health is bad, there is languor and weakness on making exertion, and the sleep is disturbed or unrefreshing. It is often disturbed in the male by priapism, seminal emission, and in the female by genital itching, amounting, in some cases, to nymphomania. A woman, aged twenty, has been affected with the last disease; four others have suffered from hysteria, epilepsy, convulsions, and even mania, from the same cause. Worms, as well as other sources of intestinal irritation, frequently induce hydrocephalus. A child supposed to labour under the last disease was ordered a large dose of calomel, which acted as a purgative and expelled some worms, when amendment took place, and in a few days a perfect recovery.

It is also recorded, that spasmodic, troublesome cough, which occurred periodically, hæmoptysis, and supposed phthisis, were speedily cured by the use of anthelmintics, or the proper medicines for worms. Morton, and other authors, describe verminous phthisis, as Dr. Wilson Phillip has subsequently done dyspeptic phthisis. It ap-

pears from the preceding statements that the signs of worms are very numerous, that there are few which are not obscure or equivocal, on account of the sympathy or relation which exists between the intestinal canal and all parts of the body. The most common symptoms are furred tongue, with a red line from the base to the summit or tip, nausea, pain in the stomach and bowels, especially round the navel, appetite lost or insatiable, belly swollen, hard, and often tympanitic, motions from the bowels confined, or fluid containing worms, or accompanied by tenesmus (a frequent forcing and apparent desire to evacuate the bowels), the urine is white or milky on cooling, and sometimes it is foetid, or very offensive.

The respiration is deranged or difficult, or attended with hiccup; there is a dry, convulsive, or suffocating cough; the voice is changed—may be weak, feeble, or entirely suppressed (aphonia).

The circulation and pulse, also, present anomalies; the heart often palpitates violently, the pulse is frequent, hard, or intermittent, and sometimes there is occasionally bleeding from the nose.

Children subject to worms have inquiet or disturbed sleep; those that are weaned grind their teeth, they are giddy, and have singing or noise in the ears. The eyes may be fixed and without expression, there is a bluish circle about the lower eyelids, the pupil is often very much dilated, the conjunctiva is sometimes yellow or jaundiced, there is itching or discharge from the nostrils, the countenance is pale, yellow, or leaden-coloured; there is lassitude, restlessness, extravagance of actions, emaciation, remittent or hectic fever, paralysis, convulsions, and sometimes death.

These are the commonest symptoms of worms, though they may accompany many other diseases. They are said to vary according to the species of worms contained in the alimentary canal.

Thus, in ascariides, there is itching, gnawing, or insupportable pruritus or irritation in the rectum. The lumbricus (*ascaris lumbricoides*) excites pain or irritation in some part of the small intestines, stomach, or about the navel.

Tænia is suspected when there is a sense of weight in the abdomen, and a sense of gnawing in the stomach. Van Swieten said he had observed rumbling in the bowels; and Haller was of opinion, that this species of worm was most troublesome at the first or last quarter of the moon. Another singular opinion was that of Butler, who supposed that worms were not injurious to children, but ought to be considered as a sovereign remedy which nature employed to free the intestines from impurities, by augmenting the peristaltic motion. Dr. Parr thought worms conducive to health. It is unnecessary to expose the absurdity of this opinion.

It appears, from the preceding statements, that it is extremely difficult in many cases to determine the existence of worms, and that the symptoms may arise from other causes, especially from irritation in the stomach and bowels, from teething, and disease in the head or chest. Keeping this fact in view, we should avoid the popular error of suspecting worms whenever a child is ill, or has the usual symptoms; and refrain from the erroneous practice of exhibiting anthelmintics too long or too freely, as these are calculated to aggravate intestinal irritation, inflammation, or ulceration. We daily see numerous cases at the hospital and dispensary, among an average of eighty patients, of children affected with intestinal irritation, accompanied by all the symptoms of worms already described, which are cured by changing the diet, exhibiting mercurials and tonics. These cases are what are termed infantile remittent fever by writers, and worm or teething fever by mothers. They are generally cured though a single worm is not passed during the treatment.

Verminous, or Worm Fever, is by no means so common a disease as is generally imagined, nor can I understand the possibility of its occurrence as an epidemic, as stated by some writers. I have observed, and successfully treated, many cases of this supposed fever, without the discharge of worms. I shall describe its symptoms and treatment under the head of *Infantile Remittent Fever*.

Treatment.—It is generally admitted, that persons in delicate health, and whose digestion is bad, are most liable to worms. It has also been remarked, that parasitic animals chiefly infest delicate plants as well as animals.

The indications of treatment are based on this conclusion, and are first to prevent the development of worms, by strengthening the system by bitters and other tonics; and second, to expel them. To fulfil the first indication, we exhibit tonics, which excite the fibres of the digestive canal, improve digestion, and prevent the accumulation of mucosities, which serve as a nidus or bed for worms. It is on this principle that the infusion and syrup of rhubarb are so efficacious in cases of very young infants. The general health should be improved at the same time by nutritious aliment, exercise in the open air, friction on the body and other hygienic means. A vast number of remedies have been proposed for the removal of worms, many of which are now considered useless. These remedies are termed anthelmintics or vermifuges. The chief of them are drastic purgatives, which, by acting powerfully, cause the expulsion of worms. The mucosities in which the animals are imbedded are partially expelled, their bodies are exposed so, that anthelmintics may come into contact with them, and destroy them. These

remedies are divided into two classes; 1, those which operate chemically or mechanically; 2, those that destroy worms by poisoning them, or by other means.

In the first class we rank all drastic purgatives, all the oleagenous vermifuges, as castor oil, oil of cloves, beech-nut, olives, turpentine, croton, tiglium, &c., sulphur, tar, sea-salt, muriate of soda, filings of tin, quicksilver and its preparations, cowhage, &c.

The second class includes male fern, heliobore, tansey, savin, rue, dittany, tobacco, worm-seed, bark of the bulge water-tree (*Geoffræa inermis*), cabbage tree, spigelius, and scabioria Indica.

These remedies require the greatest prudence in their administration, according to the age and strength of constitution of the patient. I shall enumerate the simple and compound remedies most generally employed for the different species of intestinal worms, and once more refer to the rules I laid down on infantile therapeutics, and to the frequency of intestinal irritation, inflammation and ulceration in supposed cases of worms, which will be aggravated and rendered fatal by anthelmintics. Purgatives act by dislodging the usual contents of the bowels, and the accumulated mucus which covers the bodies of worms, so that a vermifuge may be applied to them. It often happens, that it is only after a free use of purgatives, a single dose will expel one or many worms, and we can only account for this result upon the foregoing principle. Brisk cathartics should always lead the way, as children's bowels are generally loaded with mucosities. Some suppose that the oleagenous purgatives intermix with the intestinal mucosities, block up the respiratory pores of the worms, and thus destroy them. These and other remedies are most useful when the worms are in the stomach and small intestines, as they can, under such circumstances, come in direct contact with them, in an undiluted and undecomposed state, which is not the case when they have to traverse the whole digestive canal, in those instances in which the insects are in the rectum. These remedies are useful as clysters, when worms are in the rectum; but they are by no means invariably successful when used either way; one of the best anthelmintics is oil of turpentine, as it acts as a powerful purgative, and often comes in direct contact with all kinds of intestinal worms. It may be administered in a well marked case of worms, of whatever species, in the dose of from twenty to thirty drops, with half a tea-spoonful of castor oil, to an infant between one and two years old, but the dose must be increased or diminished according to the strength of each patient. It has been administered to adults in the proportion of one to three ounces, or two middle-sized wine-glasses full. An ounce, or two moderate table-spoonful, have been exhibited to a child of ten years old. It must always

be recollected, that oil or spirit of turpentine is a very dangerous medicine in large or excessive doses. It has caused giddiness, intoxication, violent purging, and discharges of blood from the bowels and bladder. It ought only to be prescribed by an educated medical practitioner. I have given a very full account of this remedy in my translation of the New Practical Formulary of Hospitals, 1835. It is generally used for tape-worm. The Hungarian balsam, so lauded in cases of worms, is only oil of turpentine, produced by the *pinus sylvestris*, and sold at a most extravagant price. It is given alone, or combined with castor oil, to infants and adults affected with worms. It is, however, rarely administered in cases of infants and children.

The empyreumatic oils of petroleum or hartshorn are now seldom used as anthelmintics.

Sulphur and sulphurous mineral waters are seldom employed or depended on at present in cases of worms. I have fully described the latter in my treatise on Mineral Waters and the Formulary already mentioned.

The muriate of soda, or common table salt, is still very much employed, both by the mouth and rectum. Mr. Leigh Thomas related a case of a gentleman, in the Transactions of the London College of Physicians, vol. 1, who took two pounds of table salt in water at once; it purged and vomited him, and caused the expulsion of a large quantity of mucus and a prodigious number of ascarides, after all other remedies had failed. He repeated the dose, though it caused severe strangury, was followed by the same effects, and effectually cured him. It is scarcely necessary to observe, that this would be a dangerous dose in most cases of adults.

The filings of tin, in the dose of from 3ij—3viij, mixed with treacle or honey, is a successful remedy against tape worm. Many unprincipled men sell the powder of lead for that of tin, as it is much more easily prepared. This may act as poison, and should never be employed.

Quicksilver, also, acts mechanically, and has been given in immense doses. It is now rarely if ever employed. Various preparations of this substance are favourite remedies; though many families object to them, if called mercurials or mercury. I need not remark, that mercury is as safe as milk, if used judiciously. It is scarcely necessary to observe, that calomel may be given in much larger quantities to infants and children, than to adults, with far greater safety. In croup and hydrocephalus it is urged to an extent that few adults could bear. I have fully described the effects of this and all other mercurial preparations in my translation of the New Practical Formulary of Hospitals, already quoted.

Another very powerful remedy for worms

is *dolichos pruriens*, or cowhage. It was first employed by the planters in America, mixed with treacle or honey. The syrup is generally preferred in this country. The dose is from twenty to sixty grains to a child under two years old, and double this quantity for an adult. The medicine was originally given for three successive mornings, and then a full dose of rhubarb was administered. Dr. Bancroft stated, that it expelled every kind of worms, and never failed in hundreds of instances.

Many of the formerly lauded vermifuges, as worm seed, tansey, savine, rue, dittany, dittany of Crete, fraxinella, angelica, and many others, are seldom or never employed in this country at present. They are still used in continental Europe, and the prescriptions are given in my translation of the New Formulary of Hospitals.

The angelica archangelica is much praised by Linnæus as a remedy for the gordius or hair worm, which is endemic in Lapland. The fresh juice of assafœtida is also lauded by Hoffman. It is said that one drachm of this smells stronger than one hundred pounds of the assafœtida of commerce.

The hellebores are too violent for common use, and are now seldom employed as anthelmintics. The seeds of cavadilla are given in foreign countries in the proportion of two grains to an infant from two to four years old, eight grains to a child of six years, and ten to a child from eight to ten years of age. Gamboge, scammony, and aloes are old and favourite remedies.

The cabbage tree and bastard cabbage tree, in the proportion of an ounce to a pint of boiling water, are said to be efficacious remedies for worms. Dr. Rush stated that he employed thirty pounds weight of the first without a single failure.

The male fern is lauded in Germany, and strongly abused by Cullen. It was the specific of Madame Nouffer. It is said by some modern writers, that it will kill the *tænia* or the patient. It is seldom employed in this country at present.

Foreign writers recommend Indian pinks, and worm grasses, which are considered two violent purgatives.

Tobacco is also a powerful anthelmintic.

Foreign Medicine.

State of the Medico-Legal Doctrines concerning Insanity in Germany. By M. Taufflieb.

(Concluded from page 211.)

THE second question runs thus—If monomania consists in the confinement of the intellectual functions by a predominant idea, should not an individual be regarded as monomaniac whose mental faculties are swayed

by a strong affection, by a violent passion? or in other terms: should not the existence of monomania be admitted or rejected according as the reason of the individual shall have been disturbed by an *erroneous conviction* or by a *violent passion*? To this question the German medical jurists have paid particular attention, the more, as the manner in which it has been sometimes solved, led to the authorization of serious abuse, some having sought for justification, even in the culpable passions of the accused. In so complicated and difficult a matter, it will be necessary to proceed with some order in the exposition of facts and opinions, and, above all, examine the subject in its different points of view, and dwell on the disputed doctrinal points connected with it.

A. It may first of all be asked, whether a strong passion, in one whose reason is habitually sound, can momentarily so far disturb the mental faculties as to render him incapable of properly appreciating the moral character of some of his actions. The possibility of such a state is admitted by all medical jurists, and numerous facts in daily observation might be brought in support of the opinion. Hoffbauer even considers that there are many degrees, "in the momentary aberration caused by the passions and inordinate movements of the mind." Thus, for instance, a sudden emotion in a person convicted of falsehood, may only produce a slight perturbation that does not deprive him of the power of reflecting on his real position: whilst a violent passion, such as revenge, is sometimes sufficient to do away with all reflexion.

B. If strong passions are capable of producing a momentary aberration of reason, should this kind of transitory alienation be assimilated to monomania? This question has most generally been answered in the negative: the most celebrated authors have vehemently protested against the tendency of some physicians to confound the momentary aberration produced by the passions with an actual state of disease. But whilst the passion in question may be the consequence of a monomania as well as of violent passions, it never *constitutes* monomania, and to maintain the contrary, would be taking the effect for the cause. Now it should be remembered that it is the *cause* of the intellec-

tual perturbation, that it is more particularly necessary to establish in criminal matters. The judge does not ask the physician whether the crime has been committed in the agitation of a violent passion, or in the calm mood of a cool premeditation—such data are furnished by the several deeds of the process; he wishes to learn whether any disease, independent of the volition of the accused, disturbed his reason at the time of committing the act. Thus put, the question leads us to examine whether a violent passion, *considered as the cause of intellectual disorder*, can be likened to a disease, that is, to a disease existing *per se*, without any participation on the part of the person affected with it; (remark that there is no monomania but on the latter condition).

The answer admits of no doubt. Henke, Heinroth, Clarus, Feurbach, Wildberg, and others exclaim against such a confusion of ideas. "There is this essential difference," says Henke, "between violent passions and a mental disease, that the former may be mastered by a man in possession of his reason, whilst an insane man can do nothing, by his own will, against the disease whose victim he is*." And the majority of German medical jurists have given a similar opinion.

C. Can a violent passion become a cause of monomania, and this once established lead to acts of violence and even to homicide? Physicians that have made observations on a great number of insane, answer this in the affirmative. There can be no doubt that a strong passion, such as fear or jealousy, may after a lapse of time alter the reason, and an instance of this has been given. This may even occur in cases where the affected person has striven to combat the emotion that caused his misfortune. Now, ought one who commits a crime in such a state of mental faculty, to be considered as having acted as an impassioned or an insane man? Dr. Elwert's conclusions from the case of this kind mentioned above, are the answer to this question. But we may go further back, with Heinroth, whether an actual mental alienation, *the result of culpable passions*, can be advanced in excuse of the insane person, or

whether a responsibility guided by the causes of the alienation, which is in some degree voluntary, should be admitted? This question, which is not a medical one, will be hereafter alluded to.

D. According to several German jurists, there is a mixed, abnormal condition of the mental faculties, in which a mixture, as it were, of passions and madness may be observed. Under this head, that morbid disposition called by Platner *iracundia morbosa* must be placed. In the works of Pyl, Henke and Frederick Hoffman we find cases that may be referred to this category. Henke states that those affected with this kind of incomplete madness are distinguishable from sane persons by the facility with which their anger is transformed, without any reason, into ungovernable fury. They differ from maniacs in the short duration of the attacks, to which reflexion and the free exercise of the intellectual functions speedily succeed. This singular tendency to attacks of passion is ordinarily connected with divers corporeal affections, which a judicious medical man will readily discover and interpret.

In Henke's Journal a case is given that they have thought fit to refer to this state of incomplete insanity. Hortense K. and her daughter, fish-women residing at G. in Bavaria, had been taken before the police commissary for hawking. As the daughter thought proper to use most abusive language to the magistrate, she was put into prison, on hearing which Antoine K., her father, hastened to the Hôtel de Ville, met the police officer that had taken her, seized him by the hair of his head, and maltreated him in a very serious manner until he was rescued. Antoine K. was brought to justice, when his counsel set up the defence of temporary insanity at the commission of the act. M. Beck, of Weissenhorth, was employed to examine the state of mind of the accused; his inquiries led him to admit in Antoine K. a morbid tendency to attacks of fury, constituting the lesion called by Platner *iracundia morbosa*. M. Beck rested his opinion on the following circumstances, met with in the individual in question. Biliary temperament, venous plethoric constitution, derangement of the digestive organs, characterized by obstinate constipation, incipient hemorrhoidal affection, sanguineous

* Henke's Lehrbuch des Gerict. Medicin. § 284.

congestion of the head. To these symptoms, which denoted a hypochondriacal constitution, might be added a considerable degree of nervous excitability, excess in spiritous fluids, neglected education, extreme affection for his family, which affection had been terribly outraged by the punishment of some members of it. Lastly, the cicatrices of former wounds which he had received in several quarrels that he had been engaged in were in some sort a visible evidence of his extraordinary tendency to paroxysms of anger. The conclusions of Dr. Beck were therefore adopted by the court, and the man was acquitted.

Perhaps the mental lesion in question may be thought to have been too readily admitted, and for reasons that do not rigorously prove the existence of a mental disease in the accused. It is also probable that other medical jurists would have given a more severe judgment of the case. In fact, if we compare this case with one that came under the observation of Professor Clarus some years ago, we shall perceive nearly similar psychological conditions interpreted in a totally different manner. It was the case of an individual who killed his mistress from jealousy. He had been hypochondriac for several years, and exhibited physical signs resembling those that obtained in Antoine K.: moreover he had been for several years tormented with all sorts of hallucinations and sinister visions that appeared to have exerted a certain influence over his morals. In his consultation on this man, M. Clarus remarked that the physical symptoms denoting sanguineous congestion of the head, irregular digestion, &c. indicated a predisposition to mental maladies, but were no proof that such disease actually existed in the individual exhibiting them. M. Clarus does not deny that the great excitability of these persons renders them much less capable of resisting the causes that could induce inordinate commotions of the mind, and thus make them certainly not of sound estate. But, says he, it is the judge's place, in punishing, to weigh these relative difficulties, which doubtlessly diminish the culpability, but do not rid the act of it altogether. The physician being called upon to state whether the accused was morally free or not at the time of the act, should only allow the impossibility of resistance from reasons that fully

establish such impossibility: in other words the difficulty of resisting ought not to be confounded with the impossibility. Clarus therefore came to conclusions opposed to those of Beck, on a very similar case*.

Third question.—*What data does our medical knowledge of monomania and the delirium of the passions furnish, relative to the questions of culpability and penalty?*

1. Monomania being a partial delirium connected with a single or very few objects, it may be asked whether the monomaniac is responsible for actions that have no connexion with the object of his delirium? M. Hoffbauer maintains that such acts should certainly be valid in civil law, and culpable in criminal law. "There is no reason," he says, "why a man that fancies his feet to be glass, and who is otherwise in good health, should be incapable of planning, or excusable for enacting criminal actions foreign to his fancy." M. Henke has not treated of this question specially, but, proceeding on the principle that the insane are only excusable in the acts of violence, because they are deprived of moral liberty, he leaves to physicians the office of examining whether that liberty has been really encroached on by a disease.

2. With regard to the distinction drawn by medical jurists between true monomania and the delirium of the passions, it is requisite to inquire what weight this medical distinction should have in the manner of judging of and appreciating the culpability of an accused person. It should be first of all remarked that moral liberty being the essential and fundamental condition of all responsibility, it should be looked on as the starting point in the discussion of questions of culpability. But as the laws have sometimes specified the causes of the abolition of moral liberty (mania and lunacy for instance), jurists have endeavoured to connect with special causes the different conditions of irresponsibility that may be presented, in order to remain, as near as may be, faithful to the letter of the law. As regards the physician, the reasons for irresponsibility only exist in nature, and there he seeks them rather than in the definitions of the law. Proceeding thus,

* Trial of the murderer Woyseck, in Henke's Journal, 1824.

his office appears more particularly to consist in determining whether the accused has been morally free or not, and next, whether moral liberty has been done away with in him by his own fault, or without the slightest co-operation on his part; and such is the mode that has been defended by Henke, against those medical jurists who would confine the question within the narrow limits of juricon-sult definitions.

A. We have already seen that the delirium of the passions should not be confounded with monomania: how then should it be considered in criminal justice? And can it be advanced as a justificative datum for the accused? M. Henke lays it down that extraordinary passions are capable of abolishing moral liberty, but that this circumstance does not justify the accused: for man, being a rational being, ought to master his passions. This opinion differs from that of M. Amelung, who thinks that regard should be had to certain temperaments, the bilious for instance, in the appreciation of an individual's culpability, since such are more liable to anger than those of the lymphatic temperament. All this Henke rejects, and says no excuse can be found but in actual diseases, when such can be traced by the physician, or certain purely accidental circumstances that will be mentioned hereafter. M. Wildberg's opinion is the same. So also is M. Hoffbauer's; he thinks, however, that the action committed by a man in the wildness of passion, can only be imputed to him inasmuch as he has been able to foresee the development of the passion. A man, for instance, who insults another, and in the quarrel that ensues commits a serious crime, ought to answer for the act, because he might have put himself out of the way of the passion; whereas a person whose reason is troubled by a sudden fright, for instance, from something that threatens his life, may commit acts, at such a time, for which he cannot be responsible, any more than the cause that has momentarily alienated his reason. Such also is M. Clarus' manner of viewing the subject. M. Feberbach says that "a criminal action committed in a state that excludes moral liberty, is not the less punishable if the cause that produced that state can be imputed to the enactor of the deed*."

The *excusable* exaltations of the mind, alluded to above, are, according to M. Henke, sudden terror, the fright that may seize a person necessitated to defend himself, a strong fit of anger, provoked by some outrageous calumny.

B. Admitting that the delirium of passion only destroys the responsibility in so far as this alienation has not been the effect of a culpable cause, should not this restriction be extended to permanent alienation, the causes of which may be imputed to the patient? It is undeniable that anger or jealousy are not so apt to produce a permanent insanity as a momentary alienation; and as in transitory delirium the accused is responsible for his actions whenever he is responsible for the causes of his delirium, it would appear natural to apply these same principles to permanent alienation. M. Heinroth observes, that "justice and humanity demand that the rigour of the laws should not be applied to wretched lunatics, who are already sufficiently, by the consequences of their faults, in their social demise."

C. Medical jurists have had a care to establish a distinction between the passions, properly so called, and certain morbid impulses of the senses, constituting a veritable disease, capable of abolishing reason and leading to excesses. Of this kind are, for instance, certain neuroses of the genital organs, the attacks of which are complicated with an actual mental alienation. According to the principles already laid down, a simple transitory alienation of reason, so long as it is produced by a disease, that is, by a cause independent of the will of the accused, ought to be looked on as a reason for excluding responsibility. Such diseases are, however, extremely rare: and M. Henke remarks, that the examination of them should be very strict, lest we should be consecrating immorality, by too readily attributing to a disease, excesses that are the effects of a libertine career alone.

In summing up what has been detailed in the preceding pages, we arrive at the following conclusions:—

1. The German medical jurists are agreed in the admission of a monomania dependent on a peculiar condition of the affective faculties and the will—instinctive monomania.

2. The only difference of opinion is, as to

* Lehrbuch. 2te. Auflage, § 87.

whether, during the paroxysm, the intellect remains sound, or is necessarily perturbed.

3. Among the grounds on which to establish instinctive monomania, the physical symptoms, shewing hypochondriacism, are more particularly reckoned, as have also been epilepsy, hysteria, the puerperal state, the coincidence of some period of evolutions, as puberty, certain moral circumstances drawn from the character and habits of the patient, &c. &c.

4. Rational monomania consists in a vicious relation between the senses and external objects, according to some; while others maintain that hallucinations may exist without any monomania.

5. Instances of the several varieties of monomania appear to prove that this disease has been most generally admitted in practice, not on account of the establishment of the existence of an illusory idea in the patient, but on the certain knowledge that under the influence of this illusion the intellectual faculties were actually interfered with in their operations.

6. Strong passions may also momentarily pervert the intellectual faculties, but this is not to be confounded with monomania, which is a real disease, existing *per se*, and without any co-operation on the part of the affected person.

7. Yet monomania itself may originate from culpable passions, and consequently be the fault of the patient. According to law, however, this disease, once ascertained, precludes all responsibility.

8. The passions themselves only abolish or even diminish the responsibility of the accused in cases where they are brought into action in spite of him, and by some powerful but purely accidental cause, such as the sight of danger that threatens life.

9. There is a mental condition, characterized by a sort of mixture of exaltation, produced by the passions, and of incipient mania, which, according to those jurists who admit such a state, destroys responsibility.

10. The passions under the dominion of reason are not to be confounded with extraordinary desires that are owing to a real disease capable of producing a veritable alienation, and of leading the patient, in spite of himself, to serious excesses of conduct.

11. The habitual maniac is, according to several writers, responsible for acts that have no relation to the object of his delirium.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Concluded from page 144.)

Incision of Strictures.—The employment of incision was practised three centuries since by De Viga and Dias, and in the commencement of the seventeenth century by Mayerne in France. Doerner, La Fayer, and Viguerie employed a lancet covered by a catheter; and this was also used about thirty years ago, by Sir Charles Blicke, of St. Bartholomew's Hospital, and Mr. Nayler, of Gloucester. Sir Charles and Mr. N. soon abandoned this instrument; but it has been lately repropounded by Mr. Stafford*. His directions as to the use of this instrument deserve attention, and I shall therefore give them in his own words.

"Before using the instrument, the exact distance of the stricture from the extremity of the urethra should be ascertained. In the armed catheter, which is intended to divide strictures over the wire, which serves as a guide, the wire must be introduced through the stricture first. The mode of accomplishing this is, by passing the smallest possible-sized catheter, made to contain the wire, into the bladder. The wire, which is double the length of the catheter, and blunted at one end, so that it may not injure the bladder, is then pushed forward, and the catheter gradually withdrawn, by which the former is left in the canal of the urethra. The armed catheter is then passed over the wire, until its point rests against the stricture (which is known by means of the graduation), and being held securely in such position, the handle of the stilette is pressed gently and gradually. As soon as any impression is made, the lancets should be allowed to retire into their sheaths, and the blunt point of the instrument urged forward. If it do not pass on, the lancets may be again used as before. After the stricture is divided, the armed catheter should be withdrawn, and its place supplied by one of elastic gum of the same size. This should remain for a day or two, to prevent the reunion of the divided parts, and to preclude the possibility of extravasation of urine; and, on its removal, a bougie should be passed twice in the week, or as often as may be judged necessary, for some time; and the same treatment adopted as for stricture in general. The armed stilette, intended to divide impermeable strictures, must be used precisely in the same manner as the other, of course excepting the wire, which cannot be

* Stafford on Strictures, 1829.

introduced; and the same directions for the after treatment are necessary for both."

Mr. Stafford relates several successful cases after common and caustic bougies had failed. This plan is less dangerous and painful than cutting down on the stricture, and passing a catheter into the bladder; but to appreciate its value in a proper manner, the cases detailed by Mr. Stafford should be carefully perused. It appears to me that it would be advisable, when catheterism is found impracticable, and when the surgeon has no other resource than puncturing the bladder, or cutting through the stricture. The chief danger attending it is profuse hæmorrhage, which happened in Mr. Nayler's patient, and I have reason to know, in one of Mr. Stafford's own patients, who consulted a friend of mine, and mentioned the circumstance. He states in his work that the bleeding is inconsiderable, and that there is no possibility of making a false passage. He prefers this plan in all long existing indurated strictures.

Another operation has been lately performed in this country—cutting down on the stricture, and passing a catheter into the bladder. Before I describe this plan minutely, I must premise that Desault and Mr. Hunter incised strictures, but confined the operation to cases complicated with false passages, or to those in which the urethra had ulcerated behind the stricture, and the urine had been infiltrated into the cellular tissue of the perinæum and surrounding parts. This operation has been lately modified by Sir Charles Bell, and it has been performed by most of our hospital surgeons, as attested by the clinical reports published in the medical periodicals. Sir Charles Bell, Mr. Stanley, and the late Mr. Shaw, were, I think, among the first who employed it; and the mode of performing this operation is as follows:—The patient is secured, as for the operation of lithotomy, and the operator passes a grooved staff down to the stricture, where it is held by an assistant; the surgeon cuts down on the point of the instrument, and continues the incision through the stricture. A catheter is now introduced from the inferior part of the wound into the bladder, and the staff withdrawn. A gum elastic catheter is now passed through the urethra and the strictured portion, that in the bladder is removed, and the former passed in its place. This should be left in the bladder for several days, in order that the wound may heal over it as speedily as possible. If it should be withdrawn in a day or two, there may be great difficulty in re-introducing it. In one case the catheter was left in the bladder for three weeks, without any inconvenience*. In general, it ought to be removed in six or eight days, as it might become encrusted with sabulous or calculous matter. The after treatment should be con-

ducted on ordinary principles. In some cases the perinæum is found so much thickened, that it is difficult and sometimes impossible to discover the tract of the urethra; an example of which occurred to Desault. This operation has been frequently performed with success in the London hospitals. Desault considered it a useless one.

Another mode of incision of strictures has been proposed by Mr. Benjamin Phillips, and practised, according to him, with invariable success. It is much less tedious and difficult than that just described, and should it prove equally successful on future occasions, will be very generally performed. In cases of indurated stricture which it is expedient to remove immediately, Mr. Phillips introduces in a canula an instrument with a circular cutting edge, and when the canula is in contact with the stricture, a probe or stilette situated in the centre of the cutting portion is passed into the orifice of the obstruction, and keeps the instrument in a proper position. The cutting edge is then advanced and pushed against the stricture, a circular motion being given to it, similar to that for trephining, when after two or three minutes the stricture is removed, and the canal rendered pervious. "The operation may be performed with much facility, is wholly unattended by danger, and the pain is not much more considerable than that which accompanies the application of caustic. The operation has been repeatedly performed by me with complete success. It possesses the following advantages over caustic: that of being more completely under the control of the operator, of creating less inconvenience than is occasioned by cauterization (a single operation being under any circumstances sufficient for the removal of the disease), and of being applicable in cases when caustic, either from excessive induration, nervous irritability, or other circumstances, cannot be so advantageously employed. But, to ensure these advantages, I cannot conceal from myself the conviction that much dexterity and long experience in the use of the instrument are necessary*." This able writer is of opinion that no apprehension need be entertained with regard to hæmorrhage, either after caustic or incision, as this may be arrested, he states, by affusion of cold water on the genitals; and, if this fails, by introducing a bougie of the largest size, and compressing the penis and perinæum. Mr. Phillips seems to have forgotten the cases of profuse hæmorrhage detailed by Sir E. Home and Sir A. Cooper, already mentioned, in which all the means he advises had failed. He gives a comparative view of his success by various modes of treatment, which is so instructive and important that I cannot refrain from quoting it.

"These observations were made in one hundred and nineteen cases of stricture.

"Of these one hundred and seventeen had suffered from urethral discharges.

In 49, astrigent injections had been used.

5 had been subjected to forced catheterism.

29 had, during the progress of the disease, complete retention of urine.

6, retention of spermatic fluid.

6, catarrh of the bladder.

7, paralysis of the bladder.

13, urinary fistula.

6, urinary abscess without fistulous communication with the urethra.

4, spasmodic affection of the urethra, without organic affection.

4, urethral hemorrhage, previous to and during treatment.

14, tumefaction of the prostate.

5, tumefaction of the testicle.

8, diseases of the skin.

"This is then a fair estimate of the frequency with which individual complications occur.

Of the hundred and nineteen cases,

36 were treated by dilatation, of whom

11 only were cured by that means, and of the remainder

19 were afterwards cauterized successfully.

81 were cauterized primarily; of these

72 were successfully treated by this means.

Of the 72 who were successfully cauterized, 13 had relapses.

Of the 72 who were cauterized,

65 were treated by consecutive dilatation.

Of these, 13 had relapses.

In 7, consecutive dilatation was not employed, and no relapse occurred.

5 cases were incised by the urethrotome.

4 of them successfully, the obstruction being at once removed: in the other the operation was not completed.

"In seven cases of cauterization, when the cure was permanent, and in the four cases by incision, consecutive dilatation was not employed.

Of the thirty-six cases treated by dilatation,

4 were in persons above 60,

20, in persons between 40 and 60,

8, in persons between 25 and 35,

4, in persons under 25.

"Of those above 60, 2 failed; amelioration only having been produced.

"Of those between 40 and 60, 4 were cured and 16 failed; the reappearance of the disease soon following the suspension of the treatment.

"Of those between 25 and 35, 3 were cured and 5 failed, the disease soon reappearing.

"Of those under 25, all were cured.

"In those nine cases where cauterization failed, the parties were of the following ages: 42, 45, 58, 60, 76, 63, 69, 76, 77.

"The patients of sixty-nine and seventy-seven died of cerebral affection during the treatment; the patient of seventy-six became impatient and was lost sight of; the four younger patients, in consequence of a relapse, refused to undergo further treatment: of the other two I can give no account.

"In the 72 cases where cauterization was successful,

8 were above the age of 60;

of these were relapses 3.

24 were between 45 and 60;

of these were relapses 6.

22 were between 35 and 45;

of these were relapses 3.

18 were between 20 and 30;

of these was relapse 1.

In the five cases of incision—

4 were between 45 and 60;

these were all cured.

1 between 40 and 45, not cured.

The cases then, during the progress of which total retention occurs, are in the proportion of one in four. Those in which perineal abscess occurs are as one in six. Those in which fistulæ occur are as one in nine. Those in which spasmodic strictures, in the absence of organic disease, occur, are as one in thirty. Those in which urethral hemorrhage occurs, in a similar proportion. The cures by dilatation are as one in three. The cures by cauterization are as fourteen or fifteen in sixteen. I am not in a condition to state the proportion of relapses after dilatation: those after cauterization are as one in seven or eight; and the age which afforded the greater proportion of relapses was above sixty. Of the cases of stricture which are presented, the proportion occurring at given periods of life is as follows:

From sixty to seventy, one in twelve.

— fifty to sixty, two in eleven.

— forty to fifty, three in eleven.

— thirty to forty, four in thirteen.

— twenty to thirty, one in seven."

As there is great diversity of opinion with respect to the comparative value of these operations in cases of retention of urine, and as many eminent surgeons prefer puncturing the bladder, I shall proceed to describe that operation.

Obstinate Retention of Urine—Failure of Catheterism—Puncture of the Bladder through the Rectum, Hypogastric Region, and Perinæum.

—Retention of urine may be produced by many causes; but I shall notice the most common—namely, stricture of the urethra. A person who labours under the slightest affection of this kind, is never free from the liability to retention of urine. Irritation may be excited in urethra by various remote causes, long riding on horseback or equitation, excessive drinking or sexual intercourse, exposure to cold, more especially when the patient has long suffered from stricture, and is of an irritable habit. The symptoms of retention of urine are, an urgent desire to evacuate the bladder, pain in the organ, in the groins, loins, and genital organs, great straining, nausea or fainting, deranged pulse, thirst, and fever. Though all these symptoms exist, the patient may not be able to pass a single drop of urine, but in general he evacuates a few drops ac-

accompanied by the most agonising pain. The usual practice in such cases is to endeavour to pass a catheter into the bladder, and if this cannot be effected, to order a warm bath, fomentations, leeches to the perinæum and hypogastric region, venesection, opium, tartarized antimony, and the tobacco enema; and should all fail, the bladder must be punctured.

Various modes were proposed for puncturing the bladder, but the first was, I believe—

The Operation in Perineo.—This was proposed by Riolan in 1648, according to Heister*. Thevenin performed it in 1658†, and Folet in 1677‡; Garengot claimed the priority in 1720§. Sæmmering gave the credit to Latta. The inconveniences that attended this operation caused it to be universally abandoned. It must be obvious that there was great danger of making false passages, of hæmorrhage, of wounding the prostate, rectum, and vesiculæ seminales. Bichat objected on account of the liability to make false passages; Sæmmering, as it induced hæmorrhage, inflammation, and the presence of the canula prevented the patient from sitting or standing; Sabatier, as an operator could never be certain of the course of the trocar, and as it might not pierce the bladder, which changes its position according as it is more or less distended; while Murray, Westbretch, and Reid, relate cases in which it failed, and in which recourse was had to other modes of puncture. Callison held it impracticable when the prostate was enlarged; and Boyer maintains that it requires more dexterity than the other modes of puncture. These and many other writers object to it, and it has fallen into complete disuse in this kingdom. The next mode of operation was—

Puncturing through Rectum.—This was proposed in 1760 by Flurant, chief surgeon to La Charité at Lyons||. This plan has its advocates and opponents. Those in favour of it are Callisen, S. Cooper, Murray, Sabatier, Howship, Rainard, and Hey. These eminent surgeons assert that this is preferable to all other methods of puncture, that the puncture is made remote from the seat of the disease, and that there is no danger of urinous infiltration. They state that it more completely empties the bladder, causes less pain, as neither skin nor muscles are penetrated, and lastly, that it is more easily performed.

Those who oppose it are Boyer, Sæmmer-

ing, Chopart, Paletta, Sir A. Cooper, Carpue, and many others. They urge the following reasons in support of their opinion—that the bladder when distended may be so remote as to elude the possibility of puncture—that the canula will irritate the rectum, cause tenesmus, and prevent the patient from sitting, or lying on his back;—that the exploration with the finger is very painful to some patients—that the peritoneum may be wounded—that the existence of tumours or scirrhous substances in the bladder or rectum may prevent us from ascertaining the degree of distention of the bladder with the finger—that the vesiculæ seminales may be wounded—that it is not practicable when the retention has been induced by confusion on the perinæum, causing inflammation of this part or of the prostate; that the trocar may divide one of the hæmorrhoidal arteries, and lastly, that the puncture may continue fistulous.

The last mode of puncturing the bladder was the—

Hypogastric Operation.—This mode of operating was first proposed by Tubier*, Merey†, and Morrard‡, and was advocated by a preponderating majority of British and foreign surgeons, and is generally preferred at present. Its advocates were Heister, Côme, Lecat, Sharpe, Lucas, Lassus, Schreger, Bonn, Richter, Chopart, Desault, Sabatier, Langinbeck, Bell, Pelletan, Schimdt, Nauche, Home, Abernethy, Boyer, Ducamp, &c. These contend that the only danger that can arise from this operation is infiltration of urine, whereas this may more likely happen after the recto-vesical puncture, when it will be aggravated by the presence of the fecal matter. It is also much more probable that the peritoneum may be wounded in the lower than in the upper operation. Besides the puncture is made in the former case through that portion of the bladder which is most irritated, spasmodically contracted, and often inflamed by the urine. The necessity of removing the canula when the bowels are evacuated, is a serious inconvenience. It has been urged against the hypogastric operation that there is danger of urinous infiltration in the abdominal cavity and parietes, but this scarcely ever happens unless by great negligence of the surgeon.

Puncture of the bladder is often rendered unnecessary by the occurrence of abscesses and fistulæ in the perinæum, or in the urethra behind the stricture. Daily experience attests the truth of this statement. It is therefore necessary to describe the pathology and treatment of such diseases.

Abscesses and Fistulæ in Perineo.—Abscesses in the perinæum may be caused by external injury, or by the infiltration of urine into the cellular tissue and fat of the perinæum. When stricture renders the urethra impervious or nearly so, the patient strains violently when he has occasion to evacuate the bladder, and the consequence of such violent and repeated efforts will be irritation, inflammation of the urethra behind the stricture, and distention or rupture of the mucous membrane of the canal. This membrane becomes distended, and may admit the transudation of a few drops of urine, which escape into the subjacent cellular tissue, and excite inflammation and abscess. These effects will of course be more sudden and extensive when there is rupture of the membrane. In some cases the progress of the abscess is slow, in others rapid, and speedily terminating in gangrene. In a former page, I alluded to the dangers of urinary abscess, and stated that the infiltration might extend to the scrotum, abdominal parietes, and inferior extremities. A friend of mine has mentioned two such cases to me; and there is another recorded by Segal. Abscesses may be caused by irritation of the urethra independently of stricture*, or of the presence of a foreign body in the canal.

Ulceration or rupture of the urethra most commonly occurs in the bulbous or membranous portion, because stricture most commonly exists in the curvature of the canal, so that the portion between the curvature and neck of the bladder necessarily suffers. The rupture usually occurs in the inferior part of the membranous portion.

The abscess may be filled with pus only, or contain this and a quantity of urine. It may occur at any period of stricture when the urethra is irritable, but it most frequently happens in the advanced stage of the disease. The presence of an irritating fluid such as urine, in parts not designed to be in contact with it, will speedily excite violent inflammation and sloughings. When the disease is not treated in its first stage, we find that the skin assumes a darker livid colour, rapidly sloughs, and an exceedingly fetid fluid, composed of pus, urine, and sloughy cellular membrane is discharged. If the infiltration and sloughing be allowed to extend to the scrotum, groins, abdominal, thoracic, or femoral parietes, death will speedily take place.

In most cases, the extension of the inflammation is rapid, though sometimes the tumefaction of the perinæum is slight; but in general it is considerable, and there is little urine expelled by the urethra.

The indication of *treatment* is to give an exit to the pus, or urine, as soon as possible, by a free incision, as it would be almost impossible to expect resolution while the exciting cause of inflammation remains.

It has, however, happened, but very rarely. In some cases it will be necessary to plunge an abscess lancet to the depth of its edge; in others a slight puncture will be sufficient, when the parietes are thin. After the abscess is opened, a large poultice should be applied, and the patient of course confined to bed. The abscess should never be allowed to burst spontaneously, because then the parietes would be so thinned, the cellular tissues absorbed, that the opening could not heal. When an early opening is made, the skin and cellular tissue are divided; these tumefy or inflame, and the wound is closed by the first intention. Nevertheless, there are many cases in which a timely incision has been made, and in which the repeated irritation produced by the urine, has caused fistulæ, in despite of all of our efforts.

Fistulæ in Perineo.—It is obvious, that when the passage of the urine through the urethra is completely prevented, and an opening or openings existing in the perinæum, that the fluid will be forced through the latter. The obstacle to the passage of the urine is the cause of abscesses and fistulæ. These apertures may be situated in any part of the perinæum, around the anus, in the nates, and even, though rarely, in the groins. Nature in some rare instances makes an attempt to obviate the inconvenience of stricture, by establishing a fistula under or by the side of the stricture, and extending it in front of the obstacle. But no surgeon would be justified to wait for such an occurrence.

The indication of *treatment* is evidently to remove the stricture or any foreign body which obstructs the flow of urine through the urethra. According as the canal of the urethra is enlarged, fistulæ become closed. The practice usually employed is, to pass a catheter, however small, into the bladder and to allow it to remain there for some days, more especially if there was difficulty in introducing it in the first instance. Some remove it at intervals. The size of the instrument should be increased in proportion to the dilatation of the urethra. When the urine flows along the sides of the catheter, it is manifest that the size of the instrument ought to be increased. Difficulty is often met with in re-introducing the catheter, and in such cases, I apprehend it would be the best practice to leave the instrument in the bladder as long as it can be borne without irritation. Some surgeons advise it to be left in the organ, until the fistulæ have cicatrized, but this I consider highly objectionable. Others proposed to incise the fistulæ in perineo, but this is seldom done at present, unless the stricture be situated in the portion of the urethra correspondent to that part. It is true that an abscess may form a sinus in the perinæum independently of stricture, and then incision may be practised.

* Macilwain on Strictures, 1829. P. 147.

It often happens during the treatment of fistula, that inflammation of the testicle, and hydrocele, supervene. Both these are excited by the irritation caused by repeated catheterism, for I have already observed that an irritable condition of the urethra may produce these and various other sympathetic affections. If we keep this fact in view we can easily understand the reason why leeches and cold applications rarely succeed in removing the first disease, as its cause is in urethra. The treatment of orchitis or hernia humoralis is foreign to the title of this essay, and therefore I shall not comment upon it. So also is that of hydrocele, and I shall only venture one remark, and that is, that we should relieve the urgent symptoms of urinary abscess or fistulae, and remove the stricture of the urethra, before we attend to that minor and harmless disease. Having described the pathology and treatment of permanent stricture, I shall proceed to notice those forms of the disease denominated spasmodic and inflammatory.

Spasmodic and Inflammatory Stricture.—If spasmodic stricture is caused by a sudden contraction of a part or the whole of the urethra which prevents the flow of urine. It may be induced by any cause which irritates the canal, or it may be sympathetically by irritation in remote organs. It often occurs in nervous irritable persons, and will be induced by the passage of a bougie or catheter into the urethra, or by irritation in the digestive organs. Those who suffer from indigestion and are of a nervous temperament, may be suddenly affected with spasmodic stricture after the ingestion of certain high seasoned foods, subacid liquors, or exposure to cold. In some cases the acrimony of the urine will cause it.

Much diversity of opinion exists as regards the pathology of this kind of stricture. Some contend that it can only occur in that portion of the urethra which is surrounded by the accelerator urinæ, ejaculator seminis, compressor prostatae, and levator animusculæ; while others contend that any part of the urethra may be spasmodically contracted. According to the researches of Mr. Baur the whole urethra has a muscular covering*; but this is denied by the majority of anatomists and surgeons. It is admitted by all that the mucous membrane of urethra possesses a contractile power in a high degree, and this is proved by the fact that the canal contracts in some persons on the passage of an instrument. It is also obvious that during urethritis, before a permanent stricture is formed, the inflammatory canal will contract violently on the passage of the urine. Mr. Hunter held that when there was a permanent stricture accompanied by spasm, the disease was a mixed one, while others have termed it *inflammatory stricture*.

The diagnosis between spasmodic and permanent stricture is easily formed—in the first the patient is seized suddenly with difficult micturition, and he is speedily relieved; in the second the stream of urine has been gradually diminishing for a longer or shorter period. The first voids his urine, in general, in a full stream, but having drank freely of acid wines, champagne, sherry, &c., and passed from a warm into a cold apartment, or into the open air in cold damp weather, he finds he cannot pass a drop of urine. Confinement to bed, or warm fomentations and sedatives, such as the compound powder of ipecacuan, will relieve him in a very short time, or enable us to introduce a catheter. The hip-bath and frictions along the urethra and perinæum, with an ointment composed of two drachms of extract of belladonna and an ounce of lard, will soon produce relief. The free use of camphor with hyosciamus, is productive of immediate benefit. But it often happens that spasmodic and permanent stricture co-exist at the same time, and, according to some, the former precedes the latter in most cases. A permanent stricture is often affected spasmodically.

The urethra may be rendered impervious by acute or chronic inflammation, or by spasm. In acute urethritis there may be such engorgement of the mucous membrane as to stop up the canal, or there may be a viscid mucous secreted, which will render the passage impervious. The irritation in either case may extend to the vicinal muscles, and cause spasmodic stricture. Mental emotion may cause this complaint. Rousseau was affected with repeated retention of urine from an early age: he supposed he had calculus in the bladder. Merand made several unsuccessful attempts to introduce a catheter, and Frère Côme at length succeeded. There was no stone. The patient's fears vanished, and he seldom suffered from his complaint. His urethra was found in a natural condition after death.

The best treatment of retention of urine caused by spasmodic stricture, consists in putting the patient to bed, ordering a sedative clyster containing opium or belladonna, warm fomentation to the pubes and perinæum, and leeching the latter, when other means have failed. This plan generally succeeds; but, should retention continue, catheterism or puncturing the bladder or urethra may become necessary. Before we resort to catheterism the patient may be placed in a warm bath and bled from the arm. A catgut bougie is preferable in this case. It should be passed down to the stricture or obstruction, and kept there. It soon absorbs moisture and enlarges, so as to dilate the urethra, the patient experiences an urgent desire to evacuate the bladder, the instrument is withdrawn, and the urine flows freely. Should this fail, a silve catheter may be tried, and depletion, tartarized an-

* Home on Stricture, vol. iii, p. 26.

timony, or tobacco clyster administered. In former times forced catheterism was performed, but this is never done at present. Desault, Chopart, and Ducamp, seldom failed to pass a catheter, and seemed to think puncturing the bladder unnecessary. But the dangers of forced catheterism, as already described, very clearly demonstrate that this proceeding is fraught with the greatest danger. Mr. Brodie has however recently readvised it in retention of urine from enlargement of the prostate gland*. Delpech condemns this practice, and states that he has known death follow in a short time. Mr. Brodie, however, refers to a preparation in the Hunterian Museum, with a false passage through the prostate, the urethra being closed, and the patient survived a year afterwards. Puncturing the bladder is seldom necessary in either spasmodic or permanent stricture; but cases do rarely occur in which it is indispensable. When the urethra is considered to be plugged with viscid mucus, M. Mussat throws in an injection, and in several cases dislodged the cause of obstruction†.

The passage of the urine may be obstructed by other causes besides stricture, such as disease of the prostate gland, or the presence of foreign bodies in the urethra. I shall now proceed to describe these causes, and also some other diseases of the urethra.

Diseases of the Prostate Gland.—This gland, like all other parts of the body, is liable to inflammation and its consequences. It might appear at a first view, that it can rarely be affected on account of its position; but it may become diseased from its connexion with the bladder, urethra, ejaculatory ducts, and from its proximity to the anus.

Prostatitis may be excited by excessive venery or solitary abuses, and most especially during the presence of gonorrhœa, by urethritis, orchitis, cystitis, hæmorrhoids, inflammation of the perinæum or anus, urinary calculi, excessive equitation, and catheterism. The disease commences with a sense of weight, tension, heat, and pain in the perinæum, which extends towards the urethra, neck of the bladder, and anus. There is more or less difficulty in evacuating the bladder, or complete retention of urine. These sensations are aggravated on each attempt to empty the bladder or rectum.

There is more pain in retention of urine in this disease than in ordinary cases, on account of the pressure of the fluid against the inflamed prostate. There is violent tenesmus, accompanied by a constant desire to void the urine. There is a sense of fullness in the perinæum and rectum, and the prostate is painful on pressure, when touched with the finger introduced into the rectum. These symptoms are speedily attended with

rigors, and when suppuration is about to take place. On attempting to pass urine, a few drops only escape, and the contractions of the abdominal muscles and diaphragm press the neck of the bladder against the tumefied prostate, and completely close the urethra. The jet of urine is small, and sometimes there is complete retention. The local symptoms soon derange the constitution. The pulse becomes frequent, the skin hot, the tongue furred, and high fever is induced. Acute inflammation of the prostate often succeeds sudden suppression of gonorrhœa, continues for seven or eight days, terminates most frequently by resolution, sometimes by suppuration, but very rarely by gangrene. It often becomes chronic. When the disease terminates by suppuration, it continues longer than the period now mentioned, there are rigors and fever. According as the abscess advances, the perinæum becomes tender, tumefied, and thinner than usual. An obscure sense of fluctuation may be perceived in some instances. The suppuration does not usually occur in the gland, but in its envelope and the subjacent cellular tissue. Sometimes there are many small abscesses, at other times there is one large collection of pus. The abscess usually points to the external surface of the gland, and may burst into the bladder, urethra, rectum, or perinæum. Mr. Brodie describes numerous cases of this disease in his valuable lectures already quoted.

The indications of *treatment* are the following: first, to arrest inflammation by the most powerful antiphlogistic measures; secondly, to prevent suppuration. All authors agree as to the propriety of employing the most energetic antiphlogistic measures. (Morgagni, Petit, Chopart, Bell, Home, Brodie, Cooper, Phillips, &c.) General bleeding should precede all other means, and be followed by leeching the perinæum, cupping the loins and sacrum, partial baths, fomentations, purgation, and then sedative enemata. Absolute repose is to be enjoined in the horizontal position, the thighs should be separated, the pelvis raised so as to avoid compression. The diet should of course be low, and the liquid ingesta barely sufficient to allay thirst. Mr. Brodie advises the bowels to be opened with calomel and senna, and then a clyster composed of two ounces of starch, and a half or a drachm of laudanum. This last to be repeated every night, or even oftener, the bowels being opened by mild aperients.

During the use of all these remedies, we must not forget the necessity of evacuating the bladder, should the patient be unable to effect it by his own efforts. Desault and Boyer advised a large gum elastic catheter for this purpose; Mr. Brodie recommends a very small one without a stilette*, while Sir E.

* Lectures on Diseases of the Urinary Organs, &c. 1833.

† Leçons sur les Retentions d'Urine, 1832.

* Lectures, 1833

Home and M. Lisfranc prefersounds. When both instruments have been tried without success, we must employ the other means advised for retention of urine, and if these do not afford relief, the only thing to be done is to puncture the bladder.

When the symptoms indicate suppuration, Sir B. Brodie advises us to plunge a lancet up to the shoulders, or even to the handle, fearlessly; if there is matter, it will escape, and should there be none, the condition of the patient will be improved by the loss of blood, and the removal of the tension of the soft parts*.

When an abscess bursts into the urethra, Sir B. Brodie advises, in some cases, the catheter to be constantly retained in the bladder till the affected part has healed; but he prefers the occasional introduction of the instrument. There are, he says, cases in which the catheter excites so much irritation that it must be entirely omitted. According to his experience, most persons are cured by this plan, the general health being attended to at the same time; but some die in consequence of disease of the kidney. He has used cubebs in the dose of twenty or thirty grains three times a day, under the impression of its acting as a gentle stimulant on the affected part, somewhat similar to the action of Ward's paste in abscesses, fistulæ, and ulcers of the rectum.

Reviews.

Stammering considered with reference to its Cure, by the application of those Laws which regulate Utterance; in a Letter addressed to Dr. Birkbeck, F.G.S., &c. By Richard Cull. 8vo. pp. 50. London: Renshaw. 1835.

On perusing this pamphlet, we were struck with astonishment at the fact that the author of it has most carefully avoided the slightest notice of the physiology of voice, or the description of his method of treating stammering. He mentions some cases which he improved, others which he cured, but he has forgotten to state his plan of treatment. While he very dogmatically condemns the practice of others, he withholds mention of his own; and after the perusal of his production, the reader is as wise as before he opened it. The work is written in a quaint, bombastic, and puzzle-the-vulgar sort of style, which no general, and indeed few professional readers can comprehend. It has one great feature, however; the cures

and improvements of patients are very intelligible to all concerned.

Had the author given the latest and best physiological views of the voice, as he ought to have done, then described its pathology, and lastly the treatment he employed, the profession and the public might be indebted to him. It may be said that this mode, which, by the by, is the only scientific one, pursued by the monographic writers in all civilized countries, would oblige the author to publish a volume instead of a pamphlet; but suppose it did, might he not, we beg to inquire, have done himself, the profession, and the public, very great service? We answer, he might have done so most undoubtedly; for such a work is still a desideratum. We should be the first to applaud such a production, though we cannot but censure the impotent and good-for-nothing tract before us. Let the author only follow our advice, and if he have well observed the disorders of which he treats, he may, by a systematic treatise, acquire both fame and wealth. Let him publish a treatise *ex professo* on the subject, and he will find a hiatus that has long existed in British medicine.

—o—

A Practical Treatise on Diseases of the Teeth, in which the Origin and Nature of Decay are explained, and the means of Prevention pointed out. By William Robertson; with Plates, illustrating the Author's views. 8vo. pp. 158. London: Longman and Co.; and Belcher and Son, Birmingham. 1835.

An Essay on Artificial Teeth, Obturators, and Palates, with the Principles of their Construction and Application. Illustrated by Twenty-six Cases and Twenty Plates. By Leonard Koecker, Surgeon Dentist, Doctor in Medicine, and Surgeon, &c. 8vo. London: Highley. 1835.

CHANCE has thrown two works on diseases of the teeth before us. We have perused both with attention, and find them as different as the antipodes. Dental surgery is as yet a kind of no man's land in this kingdom. It will be said, we have the works of Hunter, Blake, Fox, Bell, and a hundred others; but we reply, every one of them is unsatisfactory. Even Hunter has not understood the pathology of the teeth, and much less his successors.

* Lectures, 1833.

Mr. Robertson, like hundreds of his predecessors, declares that he has untied the gordian knot. His predecessors and rivals have repeatedly cut it. We shall carefully examine his discovery when time allows. It would be fortunate for humanity if he succeeded. We use the subjunctive mood, though he shall employ the indicative. We know he is a highly respectable surgeon, not surgeon-dentist; and we shall have much pleasure in allowing him to speak in *propria persona*.

We have had so many treatises on the teeth, that we have often exclaimed, "Jam satis." We have seen some ascribing all disorders and diseases to the teeth, others professing magic skill in dental surgery, and all failing to afford relief except by the painful, we have reason to say horrible operation of extraction. Charms, amulets, and nostrums do not relieve tooth-ache; the terrific operation of extraction, which, sound-toothed reader, is as if the dentist was twisting off your head, is the sovereign remedy.

He has attempted to enlighten the professional and non-professional. He thinks he has untied, not cut the gordian knot. Our readers shall judge for themselves on a future occasion. In our opinion, he is a judicious and excellent dentist. We think, however, that some of his conclusions are untenable.

Mr. Koecker may be an excellent surgeon-dentist and a learned doctor in medicine and surgery, but he has frightened us with his illustrations, "by twenty-six cases and twenty-one plates." Our numerous readers know full well that we abound with the milk of human kindness, that we could not injure a blue bottle fly; nevertheless, we are very much disposed to quarrel with our author. His work, in our opinion, is written *ad captandum vulgus*. He appears to us a mechanical dentist. He is evidently well acquainted with the management of artificial teeth, obturators, and palates; but his twenty-six cases, most of which are illustrated by a plate, are only calculated to frighten the afflicted. He informs us that he is a foreigner: the very reason that we feel ourselves proud to treat him with courtesy. But when he, a doctor in medicine and surgery, according to his

own statement, publishes a work purely mechanical, and not scientific, we have just reason to criticise it, as our contemporaries in foreign nations are, in the aggregate, just as learned, scientific, and experienced as ourselves. In fine, the work we censure, will be very useful to illiterate, but we doubt, to scientific dentists.

—o—

Formulary for the Preparation and Employment of several new Remedies, such as Morphine, &c. &c. Translated from the Eighth Edition of M. Magendie, with an Appendix.
By Charles Wilson Gregory, M. D. 8vo.
pp. 225. London: E. Cox. 1835.

THIS is a literal translation of M. Magendie's celebrated Formulary, and a rival of that by Dr. Gully, already noticed in this Journal. Our readers will naturally inquire the reason of two versions of the same work. We really cannot inform them. We cannot affirm that there was a rivalry between the translators or the publishers, though we have heard, but can offer no opinion on the subject, that there was between the latter. We know, however, that Dr. Gully was not aware of this, and further, that he would never interfere between such opponents. He was requested to give a translation, and he executed one with his wonted ability, and added many valuable notes and an appendix. It is true he pruned the turgid style of the original, and for this he is indirectly attacked by Dr. Gregory. After all, this is a matter of taste. Some will prefer a knowledge of all that is useful in the original work, and others will desire a literal translation. It is fortunate that both classes of readers may be gratified on different terms. Dr. Gully has added many valuable notes, Dr. Gregory none. The former has given an appendix; the latter has selected the same subjects for another, and given verbal repetitions of some of the sentences of his predecessor. This is unfair, without the use of those trifling, insignificant, little, and crooked marks, vulgarly called inverted commas.

Dr. Gregory has executed his translation with accuracy and ability.

The Christian Physician and Anthropological Magazine. No. I. Published Monthly.

By E. Palmer.

A NEW periodical has issued from the press. We were struck with the title, "The Christian Physician;" we exclaimed, every learned physician is and must be a Christian; but when we saw, "and Anthropological Magazine," we hailed a classic brother as the sponsor. We delight in the euphony and grand eloquence of the ancient Athenians; "anthropological," relating to man, reminds us of another equally significant term, "panto-philological." Our worthy contemporaries of the Dublin Medical Journal may stare at this, and leave it to us to admire it. But we must allow the Anthropologist to come before our readers. The following is his address.

"Man, the most noble of the terrestrial works produced by the Divine Mind, is so made as to be capable of enjoying the greatest happiness and enduring the greatest misery.

"To enjoy happiness he must possess *Health*; to avoid misery he must be free from *Disease*.

"*Health* is threefold; namely, *bodily health*, *intellectual health*, and *moral health*.

"*Disease* is threefold; namely, *bodily disease*, needing the physician; *intellectual disease*, needing the philosophic physician; and *moral disease*, needing the Christian physician.

"The Christian physician embraces the philosophic physician, for true philosophy is a part of the wisdom of God, which, whether manifested in nature or in revelation, comes under the attention of the Christian physician.

"Bodily disease manifests itself by *symptoms*; intellectual disease by *error*; and moral disease by *vice*.

"The objects of *cure* before the Christian physician are, therefore, two—*error* and *vice*; and, in respect to bodily disease, the object will be *prevention*.

"It is evident, moreover, that man's avoidance of *bodily disease* is to be effected only by attention to the laws of the *natural creation*, every violation of these laws being, from the unbending and invariable nature of the laws themselves, attended with punishment, either immediate or remote. Man must, therefore, before he can be free from bodily disease, become acquainted with the *laws of the creation*, viewed in reference to his *body*; and, becoming acquainted, must act upon his knowledge. To communicate this knowledge is one of the objects of the promoters of the Anthropological Magazine, and will cause them to introduce into its pages Physiological, Chemical, and Natural History facts.

"It is equally evident, that man can never escape *error* unless he knows those truths which refer to his *intellectual condition*; in other words, unless he is acquainted with the various laws which regulate the perception and the appropriation of truth by him as an intellectual being. To develop these laws, the Anthropological Magazine will contain, each month, a *Lecture on Phrenology*, and Essays on other matters connected with the Science of *Mind*.

"It is not less true, that man can never be freed from vice unless he knows, and acts upon his knowledge of, those laws which constitute the relationship in which he is placed to his Creator, as the *Moral Governor of the Universe*, and to his *Fellow-man*, placed like himself under the same government. The Anthropological Magazine was intended for the development of these laws.

"Any one beholding the world at the present moment will perceive two things; first, that there is much error and much vice, and that men are anxiously looking forward to a better state. The waters of the human mind have been stirred previously to the healing.

"In regard to the vice which prevails in the world, and in regard to its removal, *Christianity* will be the guide; the reason of so esteeming Christianity being, that it affords the only satisfactory acquaintance with the laws regulating the *Moral government* of the universe; and therefore, while the *volume of Revelation* will be made use of to benefit man's *internal* and *eternal* condition, the *volume of Nature* will be used to benefit man's *external* and *terrestrial* condition. Thus we shall read the two *Books* God has given for our good.

"To effect these objects, the pages of this Magazine will be open to Essays, Extracts, Lectures, and Original Communications from Correspondents, no matter what may be the differences of opinion, if these differences be stated in a proper spirit; the conductors of this Magazine holding with Milton: 'And though all the winds of doctrine were let loose to play upon the earth, so truth be in the field, we do injuriously, by licensing and prohibiting, to misdoubt her strength: Let her and falsehood grapple, who ever knew truth put to the worse in a free and open encounter?'

"It is trusted, that these remarks will explain the titles by which the work will be known; titles, which however unusual, are, it cannot be denied, expressive. Know thyself, is a beautiful, a noble maxim. The realization of it is still more noble. Then man has a chance of attaining to that dignity, which the name belonging to him, *ανθρωπος*, *anthropos*, indicates, namely, a *turner upwards of his eyes*. The aim of the writers of the Magazine being this, what title better than the Anthropological Magazine could be selected?"

The London Medical

AND

Surgical Journal.*Saturday, September 19th, 1835.*DEFICIENCY OF "ESPRIT DU CORPS"
IN THE MEDICAL PROFESSION.

WE would call the attention of our readers to the letter of "A Non-medical," in another part of this day's journal. If the want of a professional freemasonry, of an "esprit du corps," among medical men, be sufficiently evident to attract the observation of those unconnected with the profession, how keenly must that want be felt by its actual members! It is felt, and but too amply manifested, in the sneaking artifices to which medical men are obliged to resort to obtain a subsistence; in the uncertainty of their remuneration; in the cavalier treatment they often experience from those they relieve; and in a thousand other degradations intolerable to men who have a particle of respect for themselves or for their calling.

In the metropolis this want of professional sympathy is evinced in the overbearing insolence of "first surgeons" and "senior physicians," as contrasted with the parasitical fawning of "assistant surgeons" and "junior physicians;" in the servile acquiescence of the surgeon-apothecary who resides in St. James's parish; in the dictum of the Sir Henries or Sir Benjamins who preside in the regions about St. James's Palace; in the *condescending* tone of the rhubarb dispenser who dates from St. George's, Hanover Square, towards the lean apothecary whose poverty constrains his will to the vending of an halfpenny-worth of jalap in St. George's in the East.

While the members of the *higher* professional circles, as they call themselves—grant us patience!—while these humbugs, we say, make use of the well bred insinuation or slanderous whisper to poison each other's reputation, the

smaller fry hiss at and bespatter one another with a virulence at once ridiculous and deplorable. We venture to say that no one practitioner is without some thorn in his side, placed there by the kind offices of a professional brother; in short the "esprit du corps" is wanting in the metropolitan faculty; the individuals composing it live *by* rather than *for* each other.

Nor is this fratricidal propensity confined to the metropolis: in the large provincial towns each member of the profession may be found at his brother's throat, or else the entire number is divided into two sects filled with envy, hatred, malice, and all uncharitableness towards each other. Such is the case in Liverpool, for instance, where national politics are obtruded into the affairs of a profession to which of all others they have least relation, and where one party in the profession, resting their hopes of advancement on the Whig, and the other on the Tory section of the purse-proud merchants, have enabled the two between them to establish a complete tyranny over the medical men; hence the latter are treated as tradesmen, the physician is obliged to send in his *bill*, the surgeon compelled to take off a discount, and while the payment of both is miserably diminutive, it is the last that enters into the head of the cotton lord; *divide et impera* has succeeded admirably at Liverpool. There too the same discord for a long time obstructed the progress of one whose name is to Liverpool, in medical science, what Roscoe's is in general literature and the fine arts—an ornament, a specimen of the aristocracy of intellect shining amid the mobocracy of wealth: we allude to Dr. Carson; latterly, since the Whig party has weighed down the opposite one in the balance of political opinion, his merits have become suddenly developed, and tardy justice has been done to his worth by his occupation of the most extensive practice in the place. What miserable absurd-

dity! when it can be shown that the physical organization of men is influenced by their political opinions—when it can be shown that morbid causes or therapeutical agents have a different operation on Whigs, Tories, and Radicals—it will then be time enough to estimate the qualifications of a physician by the peculiarities of his political creed.

Analogous instances might doubtless be adduced with reference to many other provincial towns. Even in villages where it is proverbial that *one* solicitor starves while *two* flourish, if there should happen to be two “doctors,” they are incessantly occupied, like German doubles, in working each other’s destruction. The reason of this, we suppose to be, that a man’s *person* cannot be partitioned between the two doctors, who have therefore a hard tug for it, with

“a deal of swearing

And nauseous words past mentioning or bearing;”

while on the other hand his *property* may be equitably divided between the two lawyers, who, cheerfully acquiescing in so pleasant an arrangement, preserve their mutual esteem.

We have entered into these illustrations of the general remark made by our correspondent, in order to render more striking to our brethren one great cause of their not attaining that status, and weight in the community, to which their arduous labours for its benefit so amply entitle them.

We do not however contemplate any change for the better as likely to arise immediately, even from the fullest conviction of the reality of such a cause. No improvement can be anticipated so long as the profession is frittered down into foolish and invidious grades, depending rather on the amount of money expended, than on the quantum of knowledge acquired—so long as the physician only looks wise, the surgeon only *cuts*, and the apothecary only drenches. The thing wanted is *One*

Faculty, qualifying *one* species of medical practitioner, who will not look so wise but be wiser, who will cure more and cut less, and not drench at all.

—o—

WHO INTRODUCED INTO THE PRACTICE OF SURGERY, THE SMALL LIGATURE OF ARTERIES?

To the Editor of the London Medical and Surgical Journal.

SIR—It is truly gratifying to observe the attention with which foreigners regard discoveries in science, and their laudable anxiety to render justice to the merits of all who have in any degree advanced the powers of the healing art. In this generous course, the author of the *Surgical Dictionary*, Samuel Cooper, Esq., justly claims an honourable and distinguished place among our countrymen at one time*. Monsieur Maligne, as translated by Greville Jones, Esq., ascribes the cutting off the two ends of the ligatures employed in securing divided arteries, and closing the wounds over them, to me. In this he is mistaken, as the proposition and practice belong to Mr. Laurence. What I am anxious to state is, that the merit of introducing the use of the single small round silk ligature is due to me alone, and to which, neither Dr. Jones nor Mr. Laurence, nor any one else can justly lay claim, as that great improvement in modern surgery was established by me in the Royal Naval Hospital at Plymouth, while one of the principal surgeons thereof, in the years 1804 and 1805, and consequently before the book of Dr. Jones was published.

Dr. Jones’s experiments extended to the brute creation alone, and he does not recommend a small round silk ligature, but he simply advises the use of a round one. Now, as much foreign matter in the form of ligature, and equally injurious, may be introduced in a round as a flat form, it was the diminution of irritation by the reduction of the quantum of extraneous matter, that led to my adoption of the small round ligature. There need be no dread of dividing the external coat of the artery by a small ligature, which practice is applicable to all arteries, whatever their dimensions may be. No force of ligature will divide the external coat of the artery, unless the surgeon sits down under the want of that information which he ought to possess. Certainly we have seen some operate who were never intended for surgeons, and whose operations, when finished, were by no means remarkable or inviting examples of the pure *conservative* system. There is another point of great importance, to which I call the atten-

* We rejoice in adding our testimony to the above merited eulogium.—Ep.

tion of the profession, in my essay on the ligature of arteries secondary hemorrhage; and that was the arrangement in the wounds after operations, by gently drawing them out, having cut off one half on a line with the divided artery, which I lament to say is too little attended to. Such a distribution of the ligatures in all operations is of as much importance towards the attainment of success, as the small ligature itself: indeed, I may here remark that it is of little consequence, and the observation is founded on experience, whether the ligature is flat or round, provided it is small. Should torsion succeed in arresting hemorrhage, it will be a great accession to the resources of surgery; but of this I entertain doubt, as it inflicts much violence on the artery, which will conduce to inflammation and sloughing, and consequently to secondary hemorrhage. In certain constitutions and climates it may produce locked jaw, and it appears not likely to be successful in arresting hemorrhage from deep seated wounds.

I have the honour to be, Sir,

Your most obedient, humble servant,

JAMES VEITCH, M.D.,
Hospital Surgeon, R. N.; Member of the
Royal College of Physicians, London,
&c. &c.

26, Cadogan Place, September 10, 1835.

We have been informed by those who have witnessed the operations of Dr. Veitch, that his previous arrangements were marked by circumspection and regard to the feelings of his patient, and that these operations were executed with a degree of coolness, dexterity, and self-resource when difficulty occurred, equalled by few, and surpassed by none. Dr. V., in our opinion, is to be regarded not only as the discoverer of the single ligature, but as having laid down the safest method of amputating at the hip joint.—ED.

—o—

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

(Continued from p. 181.)

Nature and duration of the Disease of which the Individual has died.—In general, putrefaction proceeds more rapidly in the bodies of those who have died of an acute than of those who have died of a chronic disease that has attenuated the body, which is sufficiently explained by the larger proportion of the fluids to the solids in the former case. It would be a curious inquiry to ascertain, by numerous observations, what in-

fluence each group of acute diseases exercises on putrefaction; for this purpose it would be necessary to inter, under circumstances otherwise similar, the bodies of persons who had died of encephalitis, pneumonia, gastro-enteritis, &c.; but this inquiry is beset with difficulties, the other causes which accelerate putrefaction being too numerous and too variable to be excluded from consideration. However this may be, we know that, *cæteris paribus*, putrefaction takes place more slowly in the body of an individual who has died of hemorrhage than of one in whom the vessels are distended with blood, as in some cases of asphyxia; that anasarctous bodies putrefy much faster on that account; that the bodies of those who have died of small-pox or any other pustular disease of the skin are decomposed with peculiar rapidity; finally, that parts in which blood has been accumulated by irritation or inflammation putrefy very readily. It is also probable that the evident change which occurs in the fluids, and even in the solids, in some acute disorders, is one of the causes which accelerate putrefaction.

Phenomena which have immediately preceded Death.—The progress of putrefaction will be quicker or slower according as death has been sudden or preceded by an illness of some days' duration, according as the mortal struggle has been long or short, and according as death has been caused by the action of a virus, which produces a change in the blood, or otherwise: the aggregate effect of these influences cannot however be estimated with any degree of precision.

Period of Inhumation.—Since putrefaction proceeds more rapidly in the air than in any other medium, it is evident, that if it have not commenced when the body is interred it will not take place so speedily as if the burial had been deferred till several hours or several days after signs of decomposition have appeared: it may even happen in summer, that a body which has not been interred till five or six days after death, and already in an advanced stage of putrefaction, may be as much decayed at the end of a month, as another body interred twenty or twenty-four hours after death is found to be at the end of seven or eight months. We thus perceive the influence of a number of secondary causes operating on the body from

the period of death to that at which putrefaction begins; as the latter never occurs till the cadaveric rigidity has ceased, it is evident that the duration of this rigidity, which is far from being the same in all bodies, must have an influence on the progress of putrefaction; this is proved by the fact, that bodies which have lost their rigidity before interment offer signs of putrefaction, while it is otherwise with those which preserve a remarkable state of rigidity. But, though it be true that the duration of rigidity is a circumstance to be taken into consideration, we know that this duration is in a great measure dependent upon the temperature, and that rigidity usually takes place only in parts that have become cold; hence the progress of putrefaction varies according as the body is enveloped in woollen or linen cloth, or is in a state of nudity; according as it has lain in a cold or a heated apartment.

Deposition of the Eggs of certain Insects.—

In summer, while dead bodies are exposed to the air previous to inhumation, certain flies lay their eggs on the surface of the skin, and these being afterwards hatched in the coffin, give origin to more flies, which may multiply ad infinitum. The insects which feed especially on dead bodies and deposit eggs on their surface are the following:—*musca tachina simplex*, of Meigen; *vomitioria, cæsaræa, domestica, carnaria, furcata; scatophaga stercoria; thyreophora cynophila; anthrenus; dermestes; hister; necrophorus; sylpha; plenus fur, imperialis; oxyporus, lathrobium; pæderus; stenus; oxytelus; tachinus; aleochara; noterus; scarites; harpalus; julus lepisma*. But it is found that for some time after death the flies do not collect round dead bodies; that still later they only hover round them, and that it is not till putrefaction is further advanced that they settle upon them and deposit their eggs; soon after larvæ are seen in greater or smaller number in different parts. If two bodies be interred at the same time, one of which has its surface covered with thousands of eggs, while the other is free from them, it is evident that, *cæteris paribus*, the former will putrefy much the sooner, because it is the nature of the larvæ to destroy our tissues for their own nutrition. The influence which insects exert on the progress of pu-

trefaction, by the deposition of their eggs, is then not to be denied.

It may here be asked, how do these larvæ, chrysales, and insects, originate at all seasons of the year, and especially the *musca tachina simplex*, of Meigen, which we have so often found on opening bodies that have been buried at the depth of from four to six feet for several months or even years? This phenomenon cannot be accounted for from a few of these flies having laid their eggs on the surface of the body, because it is observed in bodies interred during the winter, when there are no flies; neither can it be supposed that these insects, which are soft and feeble, can make their way out of the earth from so great a depth, and go forth to propagate their species: again, it is equally improbable that the insects of the air can penetrate the earth to make their way to the corpse. If we only found larvæ, or chrysales, it might be supposed that these had been in a state of torpor or hybernation, which had ceased under favourable circumstances; but we find larvæ, chrysales, and flies altogether, and many of the chrysales have yielded perfect insects. What, then, can be the origin of these races of animals? We must confess our inability to solve this question.

Nature of the Soil.—This will be treated of hereafter.

(To be continued.)

DINNER TO THE ANATOMICAL TEACHERS AT BATH.

THE anatomical class of Mr. Spender and Dr. Cowan gave a dinner to those gentlemen on Friday the 11th inst., at the Eve's Hotel, Queen-square, Bath. The following address, prepared by the pupils, was delivered upon the occasion.

MR. SPENDER AND DR. COWAN;

Gentlemen—We need scarcely assure you of the gratification we feel in addressing ourselves to gentlemen whose kind attention and solicitude for our welfare and success, deservedly merit our admiration and esteem. We are assembled this evening, prompted by a desire of expressing our gratitude for the kindness you have conferred upon us in delivering that course of lectures, to which our attention has been lately directed, during which time, that kindness has been continually increased, by your unremitting anxiety that we should acquire a competent knowledge of the subject, upon which you have treated with a

perspicuity and minuteness that was so calculated to impress it upon the minds of all, that we are compelled to say, if any of us have not made sufficient progress, it has been owing to deficiency on our part.

A further, and indeed, a special advantage which we have derived, is our exemption from the new regulations lately enacted by the Apothecaries' Company, regulations which would have protracted the completion of our studies, as we fear they will those of other young men equally advanced with ourselves, who have not had it in their power to avail themselves of similar advantages.

Though many of us, in the further pursuit of professional knowledge, will have opportunities of observing the genius and acquirements of various ornaments of our profession, yet we feel fully persuaded that your lectures will yield to none in excellence, and that it will prove a source of pleasure to us hereafter, that our first specimen was calculated to impress us with so high and favourable an opinion of that community with which we feel it an honour to be connected, and one that has incorporated among its numbers, men whose names are so indelibly impressed upon the minds of all, that it would be useless to enumerate them—men who have made such splendid discoveries as render their names immortal, and which have tended so much to raise their profession to that high estimation in which it is held by the civilized world—a profession which, amid the rapid advance of science, has kept pace with every other in its progress.

We are fully aware, gentlemen, that many are the arduous duties that await us in our future life, and that it can be no easy task to perform those duties faithfully; we trust, however, that with such examples before us, we shall do credit to our teachers as well as to ourselves, remembering that no profession furnishes such opportunities of being of use and a blessing to our fellow creatures; ever bearing in mind, that he "who seeks alone for living homage, stands a mean canvasser in the porch of Fame, and never shall his worshipped image, fixed above, claim for his memory a glorious immortality."

Gentlemen, we are shortly about to be distributed, each taking a different course to reach the same goal, and it is more than likely that none of us will ever meet you again upon an occasion similar to the present; but should some of us have that pleasure at some future day, it will not probably be before time will have beguiled us of our strength, though we shall have witnessed its flight without a sense of our change—so little do we mark its progress; but however long or short our life may be, kindness on your part, and gratitude on ours, has begun a tie that will ever be strongly entwined among the most pleasing recollections of our days.

ELECTION OF MEDICAL OFFICER TO CHRIST'S HOSPITAL.

OUR attention has been attracted for some time past by a matter of serious importance to the rising generation, which some of our contemporaries have properly noticed at considerable length—we allude to the health and education of the children of that noble institution, Christ's Hospital. For many years (there appears to be no question as to the matter of fact) the children have been, at the infantile establishment at Hertford, receiving a disease by infection, from those who had gone in before them, and again transmitting it to their successors. Now the mere agency of diseases of the scalp, or any part of the cutaneous surface, inasmuch as they do not generally involve the risk of life, are usually looked on almost as simple inconveniences by those who know not the dreadful sufferings of the patient. The adult suffers from them for years, being in other respects in tolerably good health, but the unfortunate children of Christ's Hospital sustain a double misery. They are received in health, to obtain the advantages of education, the means of such education being amply provided; they become diseased, and as a necessary result—for such it has been found to be—the advantages of education, full, fair, and complete, have seldom, if ever, been obtained by them.

The questions which appear to arise to us are, first: What is the nature of the causes, and what are the characters of those diseases among the children of the Hospital, which have been considered infectious and designated ringworm, scalled head, &c.—leading the authorities of the institution to separate these unfortunate children from their school-fellows, and thus deprive them of their education?

To this we reply, as we think has been satisfactorily proved by Mr. Plumbe, that the primary causes of these diseases may be found in the dry animal diet of the children, and the cruel privation of vegetable matter, in the shape either of potatoes with their meat, of fruit with their puddings, or in any other form.

As to the characters of the diseases, they are such as we well know to be producible by a diet like that which has been heretofore by law the diet of the children of the institution, without the agency of contagion. They appear to have consisted, in a large proportion of instances, of small abscesses in the cellular membrane beneath the scalp, which destroyed the hair, and gave to the spot the character, so far as baldness was concerned, of ringworm; but very generally, as it appears to us, it would have been difficult to select, at any particular period, a few cases of true contagious ringworm from the whole establishment. Such at least we know to be the opinion of a very competent judge of the points, who has given considerable attention to it.

Looking with a kindly eye at the position of these poor children, and with anxious wishes for their education, according to the spirit of its founder, it becomes our duty as medical journalists, at the present juncture, to call the attention of our readers to the approaching election of a medical superintending officer and surgeon, the office having become recently vacant by the resignation of a gentleman upwards of eighty years of age.

Our readers are, for the most part, gentlemen of established reputation in the practice of medicine, and it is well known that the Governors of Christ's Hospital desire only such to come before them as candidates for the appointment. We say, let those go forward as candidates who have experience to allege in their behalf; for the list which has been laid before us contains names of persons not out of their pupilage! The Governors of Christ's Hospital will, we hope and believe, do what is right; but we fear alike private influence and party feeling;—the sole medical charge of eight hundred children should only be committed to a man whose personal experience has emancipated him from the influence of the mere instruction of his preceptor, and enabled him to take and establish views of his own.

If such can be found, we shall consider it a fortunate event for the children of Christ's Hospital, if he be appointed; but we are of opinion with our contemporary, the Editor of the *Lancet*, that it is incumbent on the Governors of the institution to change, and change, and change, till ring-worm be exterminated, and the course of education of the poor children run smoothly and uninterruptedly; because EDUCATION was the object of the founder, and this will be interrupted so long as ring-worm remains. In our opinion, the electors are morally bound to choose the most experienced superintendent, and one who is most distinguished for the treatment of ring-worm. They ought not to elect an inexperienced surgeon, much less a student, though there are candidates of this description who come forward to oppose a gentleman who has devoted his attention and observation for many years to the investigation and treatment of diseases of the skin, and written the best English work on the subject, and the best on the very disease which has so long existed in Christ's Hospital. We need scarcely remind our readers, that we allude to Mr. Plumbe. He has the strongest claims to the appointment, and did it rest with the profession, he would be unanimously elected. We therefore call upon our readers, on the grounds of humanity and justice, to use their influence with the governors in his favour, and to secure to the children of their fellow citizens the best medical aid that can be obtained for them. Let them urge the claims of Mr. Plumbe, our best living author on porrigo

and cutaneous diseases—one whose work are highly estimated in other countries as well as our own.

WANT OF "ESPRIT DU CORPS" IN THE PROFESSION.

—

To the Editor of the London Medical and Surgical Journal.

SIR—Nothing more surprises us of the uninitiated in medical tactics, than the inferior rank in social estimation, which the profession of medicine in all its branches is compelled to sustain. Magnificent as has been its progress in science, still its advance in the opinion of the world has been but tortoise-like. When the medical profession is compared with that of the church, the law, the army, the navy, the philosophical result would be the admission of the superiority of the first. A convenient change of politics can create a right reverend lord bishop; effrontery, and case memory, a lawyer and judge; successful accidents, a great general; but nothing but intense study, attentive practice, and constant research, with a mind of strong powers, can form a talented physician.

Then, in reason, the latter profession ought not to be of inferior regard to the others: but is the fact so? Let any man who knows the world answer the question. A doctor of divinity would be mightily offended if you were to mistake him for a doctor of medicine; thus is hypocrisy preferred to science. An officer of the army disclaims the idea of the most talented physician of the greatest attainments being permitted to sit in that House which is adorned with the political honesty of the Phillpotts and Lyndhursts, and with the bright talents of the Newcastles, and St. Albans. Now, of what use is an officer of the army to mankind? To murder—I beg pardon, to put to death persons innocent or guilty, it matters not, according to word of command, and yet such an automaton of slaughter thinks his profession (wearing the livery of a king) far superior to that of a man who assuages the ills of the human race, who often beats off death himself, and whose mind is adorned with the brightest jewels of science. But the navy it is which displays the most arrogant contempt of the medical profession. The very highly talented man, whose fate it is to be compelled to be an assistant surgeon in the navy, must make up his mind to live with boys in the midshipmen's mess. Though admitted to the honours of his profession by men of science, who have recognised him as their equal, he is not admissible as a companion on terms of equality with lieutenants and pursers. Why the capacity of weighing tobacco and measuring out rum should make a purser the superior of one whose skill is to restore the balance of nature in the human frame,

I cannot imagine. No medical man can hide from himself the fact, that his profession is not regarded with the same reverence as those which are either less useful to mankind, or else are positively mischievous. To a layman, the cause of this curious tortuosity in human opinion, appears to result from the want of concord between medical men as a fraternity. With them the fable of the bundle of sticks is verified most literally. In the army, the navy, the bar, and last, though by no means least, in the church, the *prestige* of the profession is maintained by the *esprit du corps* which actuates its members. However men of the bar, for instance, may differ in politics, or in social intercourse, the instant an attack is made upon the divinity of the common adoration, they are united to resist it; the moment that the desire appears to touch one loaf of "shew-bread," which the church calls its own, that instant the priests, the prelates, the parsons, however disunited before, high-church or low-church, Arminian or Calvinistical, elected or non-elected, evangelical or non-evangelical, broad-brimmed or narrow-brimmed, shovelhatted or unshovelhatted, all flock together, and scream at the top of their voices "the church is in danger"—take care of your souls against the march of infidelity and atheism.

With the medical fraternity, on the contrary, nothing in the appearance of union seems to exist. At war with each other (and many amongst you too ready to be subservient to the titled and highly appellated men of ignorant, useless, and mischievous vocations), the natural standing of your estimable profession is lost, and even a common parson considers himself superior to the most talented medical man. A youthful clergyman, who scarce has got from "possum to posset," would be mighty indignant if he were considered at all on an equality with a mere doctor of medicine. And a lieutenant of the navy who can manage to keep his reckoning with the aid of the sailing-master, would be very vociferous at even a hint that a medical professor was almost upon a footing with him, the commissioned, epauletted man of the quarter-deck.

The public sustains a great injury by this inversion of judgment. They learn to continue their preference to useless glitter and hypocritical pretence, and men of science, talent, and intellect, are made to yield their places in society to vice, ignorance, and vulgar assumption.

The same remarks which are thus applicable to the pursuit of medical science, attach also to almost every other branch of learning which has not been made an engine of state intrigue.

Without imitating the monopolising cha-

racter of the *esprit du corps* which animates other less in intellectual professions, the medical fraternity, forgetting all private dissensions and personal differences, should form such an union of their body, as would give them that natural standing in society to which their noble science, or rather cluster of sciences, so well entitle them.

The subject is one by no means unimportant. The natural, the virtuous, the beneficial ambition of a talented man, prompts him to exert his faculties so as to raise himself to the highest honours of the state; why then should those whose avocations are the most intellectual, alone be precluded from them, and why should a badge of inferiority be attached to the highest pursuits in which human intellect can be exerted.

I am, &c. &c.

A NON-MEDICAL.

BOOKS.

The Code of Health and Longevity, or a General View of the Rules and Principles calculated for the preservation of health and the attainment of long life. By the Right Hon. Sir John Sinclair, Bart. 5th edition. 8vo. pp. 602. London: Sherwood & Co.

[This work has been translated into the different European languages, and is one of inestimable value to mankind.]

A Dictionary of the Terms used in Medicine and the Collateral Sciences. By Richard D. Hoblyn, M.A., Oxon. 12mo. pp. 329. London: Sherwood & Co.

[A work much wanted, and very ably executed.]

A Practical Treatise on Diseases of the Teeth, in which the Origin and Nature of Decay are explained, and the means of prevention pointed out. By William Robertson; with plates illustrative of the Author's views. 8vo. pp. 158. Six plates. London: Longman & Co. Birmingham: Belcher & Son.

[For notice of this work see our present number.]

—o—

CORRESPONDENTS.

Mr. Dermott's communication requires modification before we can insert it.

A Student.—We really cannot answer for the Apothecaries' Society—he should write to the Secretary on the subject. It is clear there can be no more three months' courses; but whether attendance on the first or last three months of a six months' course will be received as formerly, we know not. We would advise students to commence in October, and not to wait until January, as formerly.

All communications and books for review are to be addressed (post paid) to Dr. Ryan, 4, Great Queen Street, St. James's Park, Westminster, or to G. Henderson, 2, Old Bailey, Ludgate Hill.

INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXX.

Hypotheses of Muscular Contraction—Summary of the Phenomena of Irritability and Life.

VI.—THE last, and perhaps the least objectionable explanation of the proximate cause of muscular contraction is founded on the presumption that it depends upon the bending at more acute angles—not as dependent on any influx of blood, but spontaneously—of the larger fibres of the muscles, in conjunction with a similar bending, first of the smaller fibres of which these larger fibres are composed, then of those of which this second set consists, and so on till we come to the primitive fibres, which likewise—as perhaps always in some degree tortuous—are all bent in the same manner (*a*). In this way it is attempted to explain how it happens that, while a muscle in general becomes shorter during its action, in proportion to the intensity of this action, it may act more or less forcibly with precisely the same degree of shortening, as in the instance of closing the jaws more or less firmly, as well as that it may sometimes act violently without any diminution of length at all, as is frequently the case in cramp. For it must be obvious upon reflexion, that while the more zig-zag direction of those fibres which run parallel with the general course of the muscle—as we may, for the sake of simplicity, suppose them all to do to begin with—must tend to shorten this organ, a similar zig-zag direction of those fibres which run diagonally with respect to the general course of the muscle—as must be the case with all those of which the first set of fibres consists upon the direction of this set becoming zig-zag—will have no effect in either shortening or lengthening it, while the same zig-zag direction of those fibres which run transversely with respect to the general course of the muscle—as many must do in the course of these repeated bendings within bendings—must tend to render the muscle longer instead of shorter than before. Hence it is easy to understand that so long as the chief seat of this bending is in those fibres which run parallel with the course of the muscle, the action of the muscle will shorten it; but that while other fibres may be called into action without any further diminution of its length, so when the latter fibres are the chief seat of the bending, or when the bending of those fibres which tend to lengthen the muscle is such as to neutralize that of those which tend to shorten it, no change whatever in its length needs take place. This zig-zag direction, as well of the minute filaments as of the larger fibres of the muscles during their contraction, appears to have been verified by microscopic observations; and the theory which ascribes the contraction of muscles to this cause does not seem to be liable to any of the principal objections which have been urged to those that have preceded it. It implies no direct connexion with the cerebro-spinal system of nerves, no immediate influx of blood, no increase in the bulk of the muscle, no presence in this muscle of principles which it pretty certainly does not contain; and it further explains more satisfactorily than any other doctrine, the increase of mechanical cohesion with which muscles during their contraction are well known to be endowed (*b*). There is, it is true, sometimes slung to this theory an appendage which, however favourable we may be to it in other respects, it is quite

(*a*) Dumas and Prevost, Dutrochet, &c.

(*b*) It has been abundantly established by Bernouilli, Reaumur, Spalanzani, and others, that a muscle during its contraction easily

sustains a weight which would have instantly ruptured it, and easily resists the entrance of sharp instruments, which would at once have penetrated it in a state of relaxation.

unnecessary to adopt—namely, that this zig-zag course of the fibres and filaments of a muscle is owing to the approximation of the transverse nervous branches with which they are supplied, and which reach them, it is said, precisely at those points where they are to be bent during the contraction of the muscle, such approximation of the said nervous branches being by virtue of galvanic attraction, or the transmission to them of the galvanic aura by the main trunks. All this appears to be gratuitous, and a great part of it absurd—to say nothing of its again involving us in all the objections already urged to the nervous influx hypothesis. Without this codicil, however, it is probable that the doctrine last stated gives the best explanation hitherto offered of the mere mechanism of muscular contraction; but at the same time it must be continually kept in mind that there is still a wide unoccupied gap between simple irritation, or the perception by a muscle of a stimulus, and the assumption, by its fibres and filaments, of this zig-zag direction, as a consequence of it. In what way the former gives rise to the latter, if indeed it do so, is still totally unexplained, and in all probability, as a process entirely *sui generis*, is totally unsusceptible of explanation—at any rate, a knowledge of the mere mechanism of muscular contraction, were it attained, would throw no more light on this process, than a description of the wheels and motions of a carriage would illustrate the nature of the power by which it is drawn forwards.

From what has been above said of the nature of irritability and irritation—or irritability called into action by the requisite stimuli—it will readily appear that the practice of speaking of irritability or vitality as of something substantial, something which may be *per se* accumulated, diminished, exhausted, is erroneous; but the error amounts merely to this, that, for shortness' sake, we speak of the *property* as directly so affected, whereas it is in fact the *substance*, of which this property is the attribute, that is so, the property however manifesting, of course, corresponding changes, since the degree of irritability in any part will necessarily be in the direct ratio of the quantity and quality of the irritable matter which it contains (*a*). But the ganglionic nervous tissue—assuming this as the immediate seat of the property in question—is of course continually renewed and consumed, like all the other tissues of the body, by molecular processes, the seat of which is the parenchyma; which thus effects incessant changes in this tissue, not only as interwoven with the substance of every other organ, but also as entering into the composition of the minute vessels of which itself consists. While the capillary arteries, therefore, are continually depositing new portions of this tissue from the mature fluid which they contain, the vessels of the veins and of the lymphiferous and chyliferous vessels are equally continually breaking down and conveying away into the crude fluids other portions of it; and so long as the various stimuli to which these two sets of vessels are exposed are natural—in other words,

It is obvious, therefore, that the weight which a muscle will support, or the impulse which it will repel after death, can be no measure whatever of the force which it is capable of exerting during life, regulated as this force is by a vital change, of the degree of which, in any given instance, as determined by the irritability of the muscle on the one hand, and the stimulus acting upon it on the other, we can form no sort of estimate. The mere physical cohesion of a muscle is perhaps as great after a long walk as before it, and when we are under the influence of a depressing, as when under that of an exciting emotion; and yet how totally powerless is it in the former cases, and how powerful in the latter! If vitality renders us almost independent of chemical science, in determining the composition of the organized body, it renders us almost equally independent of mechanical science in calculating its actions; and we may form some idea how difficult is the problem respecting the force of muscular contraction, from the discordancy of the solutions given of it by the ablest mathematicians, Borelli for example representing the force of the ordinary contractions of the heart as equal to 180,000 lbs.

and that of those of the stomach as equal to 261,186, while, by Keill, the force of the former is reduced to 5 oz., and, by Astruc, that of the latter to 3! It is unnecessary to say that the principles upon which these calculations were founded, were in the different cases very different, but their result is sufficient to show that little or no greater reliance can be placed upon any other data, than upon their degree of mere physical cohesion in determining the force of the contractions of muscles. But the fallacy of these pursuits is at present pretty generally admitted by physiologists—pity that that of chemical doctrines, in their application to physiology, is not equally obvious.

(*a*) "We are not to imagine it (irritability or excitability) as an *isolated force*, merely attached to organisms, and objectively different from their organic constituent matter, capable of change, of exaltation or diminution, without a simultaneous change in that matter. On the contrary, we are to regard it as a *quality*, founded on the specific state of the organic matter and the organization (organism), and altogether dependent on these." (Tiedemann's Physiology, by Gully and Lane, 1834, sect. 557.

so long as the excitement of any given part is neither greater nor less than it should be—the one process precisely balances the other, and neither a deficiency, nor an accumulation of this tissue, nor consequently either a diminished or increased display of irritability or vitality is the result.

Deposition, however, is a process to which inordinate excitement, however favourable it may be indirectly, by the subsequent collapse which it occasions, is directly prejudicial, the amount of the matters deposited being, generally speaking, in the direct ratio of the quantity of blood contained in the capillary arteries, operating upon them as a preternatural load, and this will of course be greater as their excitement is less; whereas absorption, on the other hand, is, like all the other processes of the living body, directly favoured by inordinate excitement, the amount of absorbed matters being, generally speaking, in the inverse ratio of the quantity of fluid which the radicles of the veins, and of the lymphiferous and chyloferous vessels contain; so that they are relieved from a part of their accustomed load, and this will necessarily be less as their excitement is greater. This is not the place for attempting to establish these facts at any length: it may be sufficient to mention here, in support of the above proposition, the mere circumstances of deposition being promoted by plethora, and of an excess of it being a constant consequence of that diminished irritation of the capillary arteries which constitutes inflammation; while absorption, on the other hand, is promoted by depletion, and by the increased irritation produced by pressure, friction, and stimulating applications of all kinds. Now, upon these principles, what must be the consequence of a greater or less excitement than natural of any part, with respect to the condition of its ganglionic nervous tissue, and consequently with respect to its subsequent manifestation of irritability or vitality? The ordinary deposition, or process of renewal, is incompatible, as has just been said, with more than the ordinary irritation of the depositing vessels, while the ordinary absorption, or process of consumption, is not only compatible with, but is favoured by a preternatural irritation of the vessels employed in this process: hence it must result that every greater degree of excitement than natural, will be followed by a proportionate deficiency of irritable matter, at once from defective deposition, and excessive absorption, and a correspondent failure of irritability, as every less degree of excitement than natural will by directly opposite effects (a). It is quite unnecessary then to receive as an ultimate fact, as is usually done, the axiom that *Irritability is diminished by every excess, and increased by every deficiency of irritation*, when it is susceptible of so simple and satisfactory an explanation. The fatigue experienced from over-exertion, which consists merely in an incapacity, owing to defective irritability, to obey the usual stimuli, and the increased energy acquired by rest, which implies nothing more than a preternatural susceptibility, owing to excessive irritability, of the action of such stimuli, are familiar illustrations of this law of the animal economy, which extends equally to all instances of irritation, whether the action which has been excited be sensible or molecular, and whether the function involved belong to those called organic, or to those called animal, in the former of which, irritation is all in all, and of the latter of which it constitutes a fundamental and essential part. It is thus that we explain the comparative immunity from the effects of intense heat, of air vitiated by various deleterious gases, or by certain contagious or infectious means, of certain unwholesome kinds of diet, and of certain poisons, of violent mental emotions, and of numerous other agents, at first highly prejudicial, acquired by long or frequent exposure to them; and it is from the same cause that we cease to experience any good effects from the most wholesome aliment, from the most salutary medicines, or from any other agent, however beneficial at first, in proportion as the system becomes accustomed to them. Among the most striking examples of this demonstration of irritability from inordinate irritation, is the diminished liability to certain diseases, which results from their having once occurred; some, like rubeola, scarlatina, varicella, variola, and pertussis, affording an immunity in general for the remainder of life; others, like the plague and yellow fever, for years; others, like ordinary typhus fever, at least for weeks, and perhaps almost every disease for some time, longer or shorter, in proportion to the character and intensity of the irritation which it occasions. In general it is only with respect to the particular stimulus, by which the inordinate irritation was in any given case occasioned, that the irritability is diminished—a fact which may be easily explained when we reflect on the almost infinitely numerous modifications of this property, any one of which alone may be readily supposed to be diminished or exhausted by one particular character of irritation. Thus the nostrils which have become almost callous to the stimulus of snuff, are still affected as violently as ever by ammonia; and the sore,

(a) Valuable as were many of the doctrines of poor Brown, he was manifestly wrong in his principle that irritability, or as he called it, excitability, was an entity imparted to every living being in a certain proportion

at birth, and that when his stock was exhausted there was an end of him. No arguments can be requisite to disprove this untenable hypothesis.

which is no longer benefited by a lotion which has been for some time employed, improves rapidly under a new, although perhaps, abstractedly, a less powerful application. In some cases, however, one kind of irritation may diminish or exhaust the irritability, not only with respect to that particular stimulus by which itself was excited, but with respect to more or fewer others; and it is thus that we must explain the immunity resulting, it is said, from the irritation produced by belladonna, with respect to the exciting cause of scarlatina, and from those produced by vaccine, with respect to the contagion of variola; nor is it improbable that many other comparatively mild kinds of irritation may in future be found capable of destroying in a similar manner the susceptibility of numerous other equally destructive diseases. On the other hand, the increased susceptibility of the action of various agents resulting from diminished irritation is very well illustrated by the baneful effects of even the most ordinary stimuli upon persons from whom such stimuli has been for some time withdrawn. Every body knows how violent are sometimes the effects of the slightest heat on those who have been long exposed to cold, and of the smallest quantity of the most simple aliment, on those who have suffered from long abstinence, and of frequent exposure to the exciting causes of diseases, and still more the actual occurrence of such diseases, renders the body comparatively exempt from their influence, a long continued freedom from such exposure is not less effectual in increasing the liability to be affected by them the first time we are thrown in their way. Upon the same principle, however, if we are more likely to be injured by deleterious agents, we are at the same time more likely to be benefited by such as are salutary, from a long disuse of them.

It will hence appear how very materially the law of irritation now under consideration must operate in keeping us, generally speaking, under almost every variety of circumstances, in a comparatively steady course; and how effectually it must tend to counteract, on the one hand, the influence of many agents calculated to do us harm, and, on the other, every attempt on our part to work miracles on our constitution, and to render ourselves invulnerable and immortal. If in proportion as we are subjected to the operation of deleterious agents, they lose a great part of their ascendancy over us, and the more carefully we recede from them, the greater is the effect which we experience from them upon every accidental exposure, and if again any beneficial agent becomes inert in proportion to the frequency of its application, while it acts powerfully when we have recourse to it but seldom, how comparatively independent must this make us, in the long run, of almost every change of condition; how satisfactorily does it explain the fact, otherwise so inexplicable, that man has in all ages existed, and does still in all places exist nearly or quite the same in all his physical characters, as at the first; and how clearly does it demonstrate the futility of a great part of the precepts of physicians in regard to many practices which they are pleased to pronounce absolutely and constantly prejudicial or the reverse! Such is the levelling influence of this law, that the greater number of those deleterious powers which, had they the same effect upon us on frequent repetition as they have the first time we are exposed to them, would soon overwhelm us with destruction, and most of those salutary agents which, did they continue after a time to affect us as they do before we are accustomed to them, would soon exalt us beyond our sphere, become in a short time comparatively inert in bringing upon us either evil or good; and if it do not prevent us from being depressed or raised for a time by numerous contingencies, it effectually preserves us from undergoing any very remarkable permanent alteration. Man is found in every climate, in every condition, from that of the most abject penury to that of the most luxurious ease, and feeding by turns on every thing which comes in his way; and what must have been the consequence had nature not implanted in him a faculty which prevents any thing from being either very bad or very good for him, except for a time, while it renders every thing, sooner or later, subservient to maintaining him in equilibrio, and to keeping the Esquimaux and the Negro, the rustic and the citizen, the beggar and the king, the same "poor, bare-footed animal" that he was originally created? It is this faculty in virtue of which we become, as it is so generally called, second nature; and this faculty, proportioned as it appears to be in all animals to their opportunities of tampering with themselves, is greater in "poor unaccommodated man" than in any other. Not only is he much more exposed in his various pursuits to innumerable evils than any other animal, but he alone of all animals is continually allowing the artificial dictates of reason to interfere with the natural impulses of instinct in the management of himself, and he is consequently much more frequently the victim of disease than brutes. But a great part of what would otherwise be the effect of his malpractices is still constantly counteracted by this safety-valve within him, which, in neutralizing nine-tenths of all the bad consequences which we should anticipate from *à priori* reasonings, laughs to scorn many of the solemn denunciations and injunctions of those who indulge in them, and by opposing every day's experience to their conclusions, has always rendered, and must continue to render them suspected and ridiculous (a).

(a) It would be amusing, if it were not melancholy, to notice the infinite attention

with which some persons are accustomed to regard the veriest trifles in the care of them-

selves, and the ardent hopes which they entertain of incalculable advantages from some established system of self-management; and it would be laughable, if it were not disgusting, to find such persons continually encouraged in their delusions by those who ought to know better. A man observes that by going for once into cold water he derives from it additional vigour both of body and mind, and he imagines that he can make himself unimpregnable and almost immortal by persevering in its use; but alas! if he shall accustom himself to it for only a week, he will find himself less invigorated by its employment than debilitated by its disuse. In like manner, a few glasses of wine to one unused to them are no doubt vastly refreshing; but he who would perpetuate their grateful influence from day to day, *may* descend into habits of drunkenness, he cannot rise into preternatural health, since it is only by exceeding custom that the body can be for a time excited, and it soon again finds its level, if it do not sink below it. We may accumulate artificial wants, but we cannot make ourselves what nature has not made us, and it is written, man is not made to be exempt from maladies, or to last for ever. The very care to preserve health is, by increasing susceptibility, the indirect cause of disease—the more rigid has been the observance of regimen, the more pernicious will be the slightest aberration from it; and one act of intemperance, or one deviation from a settled plan, shall do more mischief to the man of rule, than repeated irregularities to the habitual rake, since, in the latter case, what they gain in frequency they lose in force. Of a similar nature is in all things man's imaginary power over his own constitution. As he resolutely recedes from one hastener of destruction, he rapidly approaches another;

*“Gross riot treasures up a wealthy fund
Of plagues, but more inmedicable ills
Attend the lean extreme;”*

or if he shall be content to “use all gently,” as nature is a glutton in nothing, he will, probably, like other moderate livers, have his share of sickness and sorrow in this world, and when his time cometh, be called upon to leave it for another. Nevertheless, if one should listen to the whining of philosophers, poets, and physicians, from time immemorial, one would be led to believe, that under certain circumstances there would be no disease, and under others, no health; that he who lived in the country, on the produce of the ground which his own hands had tilled, without ambition, and almost without passions, should live on so for ever; while the miserable inhabitant of cities, in the midst of vitiated air, unnatural hours. “fresh cups, soft beds, sweet words,” should

enjoy a mere ephemeral existence, and sink into an early grave, overwhelmed with all manner of disasters. But what is the fact? The latter is perhaps less robust and ruddy than the countryman, but not less healthy; and if he have not so much strength, has still quite as much as he has occasion for, can bear many fatigues under which the rustic would sink, and in all likelihood, lives equally long and equally happily. “Toil, and be strong,” says the poet; but we must distinguish health from bodily power, as we distinguish the accurate ballancing of a pair of scales from the weights which they sustain. Our women “toil not,” neither do they spin much now-a-days; and yet they generally contrive to outlive us. The fact is, that the greater part of what is commonly advanced on these subjects, however well intended, is little better than cant; and the permanent effects commonly attributed to country air, a rule-of-three kind of diet, regular exercise, and so forth, upon *a priori* reasoning, however admirable some agents may be as remedies of disease, when our object is to effect only the temporary change in which a return to health consists, are perhaps always considerably over-rated. Vice and disease are confined to cities, and virtue and health to the country, only in the works of vapid moralists and muling poetasters; and if it is consistent with every body's observation, that man can on the one hand subsist and undergo great exertion for years together on only a few ounces of oatmeal, or potatoes and water daily, it is not less so that he can bear for years together, many pounds of high-seasoned meats and fermented liquors daily, with little or no exercise at all. We commonly, like young logicians, prove too much when speaking of the effects of practices unquestionably in some degree pernicious, and render our advice mistrusted by exaggerating these effects, and by founding our representations on what *ought to happen*, consistently with our limited view of the resources of nature, rather than on what *really does happen*, and may be observed to happen by all men. It is very shocking that persons will not always die nor continue to live under circumstances when, according to established rules, it seems incumbent upon them to do so; but such is the contumacy of nature, that, while she leaves to philosophers the privilege of determining the prognostics of every case, she always reserves to herself the right of settling the facts; and from the days of the doctors of the Sorbonne to the present, has seemed to take delight in exercising this right, to their constant mortification and discomfiture.

By JAMES MANBY GULLY, M.D.

LECTURE XV.

*Transition of Inflammation from the exterior
to the interior of the Body—General Observations.*

WE have now finished the external inflammations, the signs of which are directly perceptible; if there be any into the details of which we have not entered, we have at least laid the stress on them that they merited. You must have remarked a certain number of general facts that are common to all these inflammations, and these I shall now recal to you, as they are indispensable preliminaries to the diagnosis and knowledge of internal inflammations.

Of these facts, we shall first of all mark the tendency of inflammation to propagate, and the varied degree and nature of this propagation, according to the structure of the organs and the intensity of the affection; and next to it, the dissemination of the irritation, that is to say, the augmented movements of non-inflamed organs, and the repetition of the phenomenon of inflammation in some of them. The proof of this fact has been derived from the augmentation and diminution of the external inflammation, in which you beheld the phenomena of propagation and dissemination increasing or decreasing as the primary inflammation did, or as it was made to increase or decrease by various modifying means: and seeing this, you cannot do otherwise than consider the dissemination of the irritation, and the repetition of the inflammation, as necessarily connected with the primary inflammation.

Two distinctions in external inflammations were made when it was stated that some are circumscribed, confined to a very slight degree of propagation, and do not cause disturbance of the functions, whilst others do cause such disturbance. We inquired into the cause of this difference, and we found it in the extent and intensity of the inflammation. Connecting this fact with the preceding, we laid it down as a principle, that in order to prevent or annihilate the phenomena of propagation and dissemination, the external phlegmasia should be reduced to the most simple condition, so that it should not react on the system. The possibility of thus reducing very many of these inflammations within bounds, and keeping them there by treating them on the onset, will have convinced you of the truth of the axiom that inflammation only tends to reproduction in other organs when it has acquired extent and intensity in its primary seat, but that when limited, it

only acts on the neighbouring parts. These principles have been extensively applied to practice by men of honest intentions, who have no aim but the attainment of truth and the progress of science. In surgery, more especially, there are some who, striving to put limits to inflammation, and to crush it in the onset, have put a stop to local disorders for which operations would have been necessary, and prevented general disturbances in the system; such as traumatic, secondary, and humoral fevers, as they used to be called—medical diseases, as the expression went, that we added to the surgical malady. My principal opportunities of observing the immense difference in the results of the practice of physiological surgeons, and of those that were not so, were gained during my military career, after great battles. The latter contented themselves with immediate union, or else, after making incisions (debridements), hastened, if there was redness, to make local application of camphorated spirits, aromatic wine, or bark: sometimes for a slight contusion they lavished stimulants with the pretext of producing a revulsion or resolution, and freely gave the patients whatever they asked for, without any regard for the irritability of the organs. After a week or a fortnight of this treatment, their wards became filled with what they then called putrid or typhoid fevers, and death was abundantly busy. This sight I first beheld during the Vendean wars, and I was so struck with it, that it has never left my recollection. At that time I had abandoned the study of surgery to serve as a private soldier, and an accident having forced me to enter the hospital of Angers, I saw a multitude of wounded people die there, consumed by a burning fever and a fetid suppuration that infected the wards; the disease even attacked those who had no external affection, the pupils that dressed the wounds, the hospital servants, the *sœurs de charité*, and every one about the place.

None of this is observed in the practice of physiological surgeons: the inflammation being properly attacked, never stimulated, and the diet rigidly prescribed, no traumatic fever is seen, or only in slight degree: the typhus, which they attributed to the crowding of the sick, was no where met with; tetanus, so common in practice where antiphlogistics are neglected, is then exceedingly rare; and immense wounds and purely inflammatory diseases are thus deprived of all their frightful consequences. But a still more convincing application of the principles that I am now summing up is that which has been made in the case of lymphatic and scrofulous tumours, called white swellings. Against these diseases, though they are below the ordinary type of inflammation, immense success has been obtained by means of local and general antiphlogistics, seconded by abstinence from food and motion, compression, revulsives, and narcotics: here, at least,

the evidence of cures was irresistible, and the conviction of the rising generation of medical men has remained fixed.

Armed with these data, you are now about to plunge with me into the great question of internal inflammations, one of the most difficult problems for us who are accustomed to proceed by the aid of our senses only—a habit in which we cannot now indulge so conveniently. The locality whither the phenomenon we are considering is transported is hidden from us by a veil which we have no power to withdraw; for how can our senses penetrate the interior of the body? Nevertheless, how are we to make use of the phenomena that we observed in external inflammations? Shall we inform ourselves by comparing the inflamed parts, by seeing whether the local phenomena of the interior resemble the local phenomena of the exterior? but this is only practicable in the dead body—you cannot open the bodies of the patients you are called on to relieve; you are, therefore, reduced to the necessity of comparing with each other the inflammatory phenomena that are accessible to your senses. And what are they? I shall pass them in review by comparing the already known ones of external inflammations with those of internal inflammations.

1. *Pain*.—It is deceptive; the signs it furnishes concerning the internal condition are reducible to very few; pains may be felt in organs that are not inflamed as well as in those that are. If a patient is only prepossessed he will tell you he feels it, without having any inflammation, and will describe all the sensations he experiences: every practitioner has observed this, especially in hypochondriacs. On the other hand, an internal inflammation may exist without pain, or with pains that have no resemblance to those produced by external inflammations. Medical men that have attached too much importance to this phenomenon have often committed grievous errors, and they who, taking it for granted as constant in inflammation, have denied the latter when it is accompanied by pain, have only advanced a worthless objection. Most frequently in internal inflammations, pain disappears after a few days and sometimes even after a few hours of antiphlogistic treatment. This fact, unknown as it was, has often been the basis of arguments against our doctrines, so little advance had there been made, at the time of its appearance, in the phenomenon of inflammation.

2. *Heat*.—It should be divided into that perceived by the patient and that recognized by the observer. The former is equally deceptive with pain, because it is a sensation: the patient often has a feeling of considerable heat, though he has no inflammation, as is seen in hypochondriacs and neuropathic individuals. On the other hand, there are many cases of serious internal inflammations in which the patient perceives no heat and is intent upon other sensations; sometimes even the perceptive faculty is so interfered

with that patients have no consciousness of heat in inflammations that develop it most abundantly; on this point therefore we can conclude nothing certain from the patient's declaration. But, you will say, the observer is on the spot; the enlightened physician will perceive the heat of the inflammatory state: but this is not so easy as it at first appears. No doubt there are cases in which the heat of the viscera may be distinguished from that of the skin, for instance in some inflammations of the abdomen, where that which proceeds deeply from the bowels is distinctly perceptible, as also in inflammations of the chest, of the head, and of the spinal cord. But this is only possible when these inflammations have attained a high degree of intensity; for in the onset the inflammatory heat is rarely perceptible to the observer: in the *sumnum* the phenomena become confounded with each other and altered; in the decline, which often tends to chronicity, it can rarely be distinguished.

3. *Tumefaction* of internal organs may be met with without inflammation: it is of no value as a diagnostic sign, except it be united with other signs.

4. *Redness* does not appear, and is never seen. There is certainly a repetition of this phenomenon in the skin, and to a certain degree in the apertures of the mucous membranes: but this is not always the case: several particular causes, independent of inflammation, may produce it. It is not a perceptible sign of internal inflammations.

Behold then the four principal phenomena of inflammation, on which our diagnosis of inflammation in the exterior of the body is founded, pretty nearly useless in that of internal inflammations. What then remains? the examination of the organ after death—a late examination, it is true, but the chief foundation of our pathological knowledge. When the patient dies he is opened, and the traces of the internal inflammation that killed him are seen. But that this examination be not utterly barren, something should be made to connect it with the next case that appears. This bond is furnished by the phenomena of propagation and dissemination, which will be of the first importance to us. Hitherto you have regarded them as secondary, and in future our attention will be most especially fixed on them; in fact, how would you be able to detect in the living body, and without opening the body, the inflammation that you have ascertained in the corpse after death? You will detect it by the phenomena of propagation and dissemination, which are to be found in internal as well as external inflammations, since the local phenomena of both are the same. Leaning on this reasoning, you will observe the first patient that is presented; you will find in him the phenomena of disseminated irritation and propagated inflammation, and you will say, "this patient may have internal inflammation, though I do not see it;" he dies, and in the autopsy you

recognize the existence of that inflammation. You then have right to thank the phenomena that guided you so well. But you will perhaps ask me why I call them phenomena of dissemination? I have already told you; it is because they are the effect of the irritation transmitted along the nerves to the different organs—a transmission that first of all produces neurosis, pains or convulsions, then alterations of the secretions, sanguineous congestions, and finally, a secondary inflammation, often resembling the first. Here then is a new route opened to you by these phenomena: you already suspect, and in a short time you will positively ascertain, by their means, a host of diseases that may be verified by the autopsy when that is permitted. I maintain it, medicine can only make progress by following this rational method.

But the certainty that we arrive at by opening the body may also be arrived at by other means. The success of the treatment which has arrested the dissemination of external inflammation is presented as a fresh and powerful proof. Indeed we have seen that by arresting and circumscribing it within the narrowest limits, dissemination is prevented or made to disappear when developed, and that it may be reproduced at will by stimulating the inflammation that is its *primum mobile*.

In order to comprehend internal diseases, and become true physicians, you ought to proceed from the exterior to the interior; otherwise all will be vague and your judgments precarious, and medicine will truly be what it has been said to be, merely conjectural, and not positive, as I assert it ought to be. Not so are the positive sciences learnt: the method I teach is the only one that will make you acquainted with them; it is long and arduous as well as philosophical; it supposes all possible kinds of instruction, together with normal and pathological anatomy. Your senses especially require to be perfected by long exercise in order to preserve you from illusions and rectify the errors of your imagination. With this condition you will arrive at the diagnosis of internal inflammations. Another condition which, thanks to the intelligence of our age, now exists is, that the inspection of bodies should be permitted and frequent; on this score we have an immense advantage over antiquity; and what I have been telling you is the consequence of it—no man could tell it without the aid of anatomy. What, indeed, must the result necessarily have been of the impossibility experienced by our first masters of arriving at the verifications and the train of causalities of which I have spoken? Why, that the phenomena of dissemination were not appreciated, that inflammation was first of all only known, or very imperfectly known, in the exterior of the body, and that previous to arriving at the possibility of establishing a fair comparison between the phenomena of external inflammation with those of inter-

nal phlegmasia, an almost infinite space of time went by, during which they did nought but wander about.

It ensued from this impossibility on the part of the ancients of gaining information by the inspection of bodies, that the phenomena of dissemination were not to them signs of inflammation; that they took them for what they appeared, and not for what they really were: that they were unable to detect the hidden cause of them, and only seized on the appearances, such as the fever, pain, attitude of the patient, foul mouth, alteration of the secretions, condition of the powers in general, fetidness of the excretions, &c. Now, what are all these? symptoms. These were grouped according to their affinities, and being so grouped, were called a disease; such were the diseases of the ancients, and this is what I call ontology. When I first mentioned it to ye, many of you did not, perhaps, understand me: henceforth you will know what to think of that system of medicine before which they would have you burn incense. Most assuredly we will be among the foremost to render justice to their good intentions, to the sagacity they showed in seizing the visible phenomena of disease, to the faithfulness of their descriptions, to the care with which they weighed the phenomena, to their indications towards death or recovery, &c.; all these qualities we admire in Hippocrates, but we say, these are specimens of precision, attention, and probability, but not lessons in medicine. We would not leave diseases to go on as did Hippocrates; if we are sometimes called for too late, after they have been allowed to gain ground, we would then verify what was said by Hippocrates and Aretæus. Mentioning the name of Aretæus, I may also mention that he who knew so well how to describe the *anginæ*, did not know how to arrest them, and considered them as subject to a species of fatality; the faithfulness of this description, all admired as it is, is a thing without application. I therefore maintain, however the declaimers may erect their feathers and complain of my irreverence, and vomit forth torrents of abuse against me, I maintain that the ancients never yet transmitted to us any exact knowledge of disease, except in a very small number of instances.

You now perceive our method of getting at a diagnosis of internal diseases; it is incomparably the most sure, but has not been perhaps so easily pursued by all medical men in every country. Thus, among the Arabs and Musselmans, the opening of bodies not being allowed, could not be performed; in the greater part of the world, even in England, it is extremely difficult to obtain examinations of corpses*. In the next place, those who

* It is hard to guess why M. Broussais thus mentions England on the subject of autopsies; if there be one country more than another in which absurd prejudice exists

first performed them were more or less exact in their examination, and those that were most capable of drawing proper deductions from this rich mine of truths were not always placed in favourable positions; they met with powerful adversaries, partizans of the old systems, full of prejudices, and such as placed obstacles in the way of their useful labours becoming of good effect; so that the progress of the science which they cultivated so courageously was not regularly made. The obstacles they met with, and the disputes that ensued, caused the groups of symptoms of the ancients, put forward by them as diseases, to be maintained and perpetuated, and this the longer, as pathological anatomy was not enlightened by physiology, at that time uncultivated and left behind, and as without this main point, medicine cannot be otherwise than defective. Yet the fund of justice and truth which this new mode of investigation of necessity brought with it, was sufficient to cause people gradually to estimate at their proper value the aforesaid groups of symptoms.

Of the phenomena of dissemination, with which inflammations are accompanied, the most striking is fever. So long as an internal phlegmasia has not reached the extent of producing it, it is limited as a vague something that indicates nothing to the observer; but when it has become sufficiently extensive to induce it, every thing is in a blaze, the functions are perverted, and the patient is obliged, in spite of himself, to stop short.

By fever, I understand the acceleration of the blood's course, with an augmentation of the temperature that is sensible on the exterior of the body and in the principal cavities. No doubt you will ask me to add *malaise* to these; but it varies in the onset, and disappears towards the close; you may also desire me to add the derangement of the secretions, but this again also varies according to the intensity of the fever: *malaise* and derangement of the secretions are not such constant phenomena as the others. This fever, this tumultuous state of the blood, this *fervor*, constitutes the principal phenomenon of dissemination; and hence it is that it gave its own name to the groups of symptoms of the ancients—groups that are nothing but the disorders or congeries that follow in the train of inflammation. The fevers, therefore, of the ancients, are, in a great measure, the representatives of internal phlegmasiæ. In fact, subsequent research has verified this; one by one, some inflammations have been withdrawn from the number of fevers. The fevers depending on pneumonia, or pleurisy, or peritonitis, on certain inflammations of the brain, those caused by some phlegmonous inflammations and depositions situated in the

visceral centres, have all been in succession recognized as such. In proportion as they found it possible to attribute the systemic disorders to a determinate inflammation, the list of fevers was diminished; they have even lessened it the more as the groups of symptoms representing independent fevers, or what were so considered, ran into each other; so that at last, even with the school alluded to, fevers were reduced in number to six, by Pinel's Nosography, their great authority. As, however, the fevers of this author had not characters sufficiently marked to be unconfounded with others, his classification was not allowed abroad, nor even in France, as fixed and invariable; they took the liberty of erecting groups of symptoms different from his. According to the importance attributed by each pathologist to this or that symptom, he made it the principal of a fresh group, and as the entities or collections of symptoms represented the state of no determinate organ, they were multiplied ad infinitum. Such was the chaotic state of medicine when I commenced my criticisms of it. In short, we see that one first reduction was made in fevers to the profit of internal inflammations—what was taken from the one was added to the others. Still many febrile groups remained, that had not been referred to their true destination: the febrile condition, the basis of them, was variously qualified according to the phenomena with which it was accompanied. One individual paid all attention to the bile, another to the strength; here stress was laid on debility, there on the nervous phenomena, as regarded their regularity or disorder. Others again looked only to the excretions, to the greater or less regularity of the disease, to the degree of suddenness of its termination, to its intensity, &c. Hence came the various denominations, bilious fevers, mucous fevers, putrid fevers, pituitous, nervous, malignant, and other fevers. In all this there is abundance of arbitrary assertion, and such might be expected, especially in ancient times, from the want of post mortem examinations, and the retardation of pathological anatomy. It would be alike unjust and foolish to reproach antiquity with its powerlessness in this particular. I have never done so, and imputations to that effect directed against me, are themselves neither more just nor more reasonable than the reproach would be.

The preceding only applies to the inflammations that are sufficiently great to produce fever; but you have seen in the exterior of the body a number of inflammations that do not go so far; you have seen that even after reaching such a point, they may be made to retire within limits that cause an end to be put to the fever, without the total disappearance of the local phenomena. Thus then fever only exists in the higher degrees of inflammation, and disappears in the lower degrees; after its disappearance, a fixed degree

against the practice, it is England; the learned professor should have said "especially," instead of "even."—J. M. G.

of inflammation may persist, and be only accompanied with other symptoms of dissemination—this is the chronic apyretic state of inflammation. When things are in this condition, the confusion is great; at least, it must have been so for many long ages; and if we have happily succeeded in dissipating it, it has only been by giving to all the phenomena of dissemination, without exception, an equal attention, so that when one fails, or is wanting, we are directed by others. We hold that the disturbances produced by the state of phlegmasia are not confined to fever; that state is also accompanied by a constriction and uneasiness of the neighbouring organs to that which is inflamed; the individual is unwilling to move; he is in pain and experiences malaise; he exhibits a series of instinctive and sympathetic phenomena; all these should be seized, appreciated, and referred to their true cause. When the value of these signs is not attended to, peculiar states are made of each of them, and a hundred times more false groups and false diseases are made out of slight inflammations that produce no fever than have been created out of those that do produce it. Imagine a circumscribed erysipelas, a slight boil, a small tumour in the lungs, in the digestive canal, in any hidden organ, you not think a state of suffering, of malaise, debility, emaciation, in short, some disturbance or other would ensue? There is no occasion for imagination: the thing frequently occurs. A number of incipient phlegmasiæ are not perceived, and these have been called latent: on this point science has made much less progress than on that of exalted inflammation producing the febrile state. Under this head come neuroses, cachexiæ, occult vices, humoral depravations and corruptions, all possible alterations, in fact, and of which authors have lost themselves in never-ending descriptions and gratuitous explanations, that have generated the mass of volumes which now crams our libraries.

The opening of bodies will lead to the explanation of all these phenomena; if it has not already done so it is because an ill use has been made of it. How have anatomopathologists reasoned? They have said, here is a degeneration that was unaccompanied by fever, an alteration of organs, an organic vice; this it was, and not the inflammation that produced the symptoms. Precipitate judgment! before the alteration of the organs could be effected, there must have been an intermediate something between it and the symptoms that should have led to a prescience of it, which intermediate was either an ascending phlegmasia or a descending one ill suppressed, fixed, long persisting, and which slowly enacted the disorganization. Herein you may see the origin of a vast number of false ideas and erroneous judgments with which medicine is still infested; in other respects I am willing to confess it has

followed a better path, but it has not made all the progress it should have done.

Our task now is to reduce these two orders of diseases—of these fevers and other groups of symptoms without fever—and to refer them to inflammation, their true cause. This reduction must be effected previous to entering upon the other alterations of the human body; we must first exhaust the list of what inflammation is capable of producing, before engaging in any thing else. But you will ask me, are all fevers to disappear from the stage? They will certainly disappear if I prove that all the groups of symptoms of the ancients are referable to imperfectly considered internal inflammations; should there be any that I cannot so reduce, they will be reserved, otherwise I see not why I should respect them; it would be a culpable weakness, and cowardly on my part, were I to hesitate to overthrow them in the fear of being considered an exclusive systematist, as I have so often been falsely accused of being; it is a question that *must* be attentively canvassed. For the rest, if all fevers are set aside, and inflammation alone left in their place, have no fear that the latter will be too simple: your intellectual acumen and mine will still have more to do than they can well manage, in estimating the value of symptoms, in appreciating the action of modifying means, in referring each kind of lesion to its true cause, in directing the treatment and dietetics, in determining whether to act or not against the disease, to leave it to itself, &c. &c. No, no, medicine will never be too simple, and may still be matter of labour to the most powerful intellects for many ages to come.

I have told you my method: if I stray from it remind me of it.

—o—

CODE OF UNIVERSAL GENERATION.

SECTION VIII.

Generation of Mammiferæ or Animals that supply Breast-milk.—Mammiferæ differ from all other animals, in producing offspring which they nourish with breast-milk. These animals have perfect organs of generation.

It is in the uterus or womb, a fibrous or muscular organ situated between the hip bones, and in the pelvis, in which the offspring of the mammiferæ are developed and nourished during pregnancy, while they acquire a degree of strength sufficient to enable them to enjoy an independent and individual existence. This organ is situated between the bladder and rectum, resembles a moderate sized pear, with its apex inverted; it is about two inches and a half in length in the unimpregnated state after puberty, its sides nearly an inch thick, and its cavity of an irregular form, sufficiently capacious to contain a blanched almond. It was compared to a bottle by the ancients, and said to

have an orifice (os uteri, os tincæ), neck (cervix uteri), a body (corpus), and a bottom (fundus uteri). Its fundus or broadest part is superior and towards the abdomen. The uterus may be said to be triangular, with its base upwards towards the abdomen, and its two sides descending so as to unite at its orifice, which opens into the vagina. In each of the upper angles there is an orifice of a tube (the Fallopian or uterine), while the passage in the neck of the womb, which opens into the vagina, is about an inch in length, and is so small as scarcely to admit a probe or crow's quill—in some cases no more than a bristle—and in those who have had children, a goose's quill, and sometimes a substance as large as the point of the index finger. The orifice of the womb has two lips, an anterior, which is the thicker, and a posterior. It is in general within from two to four inches of the external genital aperture. The neck and orifice of the uterus descend into the vagina about an inch. The upper tubes (Fallopian or uterine), are about three inches in length, extending from each angle of the uterus transversely; their extremities are loose and fringed (fimbriated), and are nearly in contact with the ovaries. The use of these tubes is to allow the male fluid, or a vapour arising from it, to pass from the womb towards the ovaria, which the loose extremity seizes during copulation, so that one or more vesicles, ova, or eggs, in this last organ may be vivified, and the new being conveyed into the womb. This fact has been attested by repeated dissections, by ligatures on the tubes in animals, and by tubal pregnancies. The external and internal organs are supplied by the same nerves, and are all excited by copulation. (For ample proofs of these facts, see editor's or other recent works on obstetrics).

The ovaries (testes muliebres, female testicles) are two oval flattened bodies, each of which is attached by a ligament to the uterus, beneath the orifice of the Fallopian or uterine tube. Each has a firm smooth covering, under which is a number of ova, eggs, or vesicles, varying from fifteen to twenty in number; some of these are very superficial on the surface, and are ruptured during a prolific copulation. According to late writers on physiology, one or more vesicles, after being impregnated by the male, are detached from the ovary, and leave a mark or cicatrix, which, from its yellow appearance, is called corpus luteum; but the experiments made by Haighton, Blundell, and many others as well as myself, prove that such marks may exist in virgins and animals that had never been impregnated*. Lastly, the vagina is that passage or canal which extends from the external genital aperture (vulva, pudenda &c.) to the womb. It is lined by mucous membrane, like all passages in the body, and

this is wrinkled in the virgin state, and the folds are called rugæ, which no longer exist after marriage, and especially after parturition. This canal has also a muscular coat, which enables it to dilate, so as to allow the passage of an infant, and to contract immediately after delivery to its ordinary size. This is an admirable precaution of nature, as it enables the sexes, if adults, to cohabit, however disproportioned in size, by using gentleness and caution. In some cases, however, the vagina is impervious both in its course and external orifice, and then, unless the defect be remediable by surgical operation, which it may or may not be, sexual intercourse cannot be accomplished. It could not be effected between an adult and a female child from the age of seven to ten or eleven years—indeed before puberty, when the sexual organs are developed, without more or less laceration. In some cases marriage cannot be consummated*.

If the vagina, uterus, uterine tubes or ovaries be diseased or destroyed, incurable sterility will be the consequence. The sexual apparatus of the male is composed of the following organs; 1, an external organ (penis, membrum virile), capable by venereal excitement to become enlarged, elongated, hard and firm (erected), so as to be suited to penetrate into the vagina; 2, glandular (organs, testes, testicles), destined to secrete a fluid, without which the ova, eggs or germs of the ovary, cannot be fecundated: this fluid is called the spermatic, seminal, or prolific fluid; 3, the canal from each testicle, which conducts the seminal fluid through the groin into the pelvis, and to the under surface of the bladder, where it is deposited in a sac on each side (vesiculæ seminales), in which it accumulates until the time of copulation; 4, two other canals or tubes, one from each seminal receptacle (ejaculatory ducts), whose use is to transmit the spermatic fluid into the urethra or genito-urinary passage in the penis, whenever it is ejected into the vagina or uterus. Thus the testicles prepare the spermatic fluid, the canals (vasa deferentia) convey it to the seminal vesicles or receptacles, these retain it until it excites amorous impulse, when the other canals (ejaculatory) transmit it into the urethra, and the urethra deposits it in the vagina. An impervious state of any of these canals is opposed to procreation, and thus in case of bad stricture fecundation cannot be effected.

The accumulation of the fecundating fluid in the seminal vesicles excites the whole genital organs in man, which cannot cease until the fluid is expelled. He then approaches the female of his species, and relieves himself by the act of reproduction.

* Professor Montgomery denies this.—*Cycl. Pract. Med.*

* See the chapter on Disqualifications for Marriage, Impotence, Consummation of Marriage, &c.

During this act, all his organs are excited, and the genital more especially, as these are supplied with the same nerves. The female organs are intensely excited, so that the moment the seminal fluid is deposited in the vagina, or according to some, in the uterus, whence it is conveyed to one of the ovaries, an ovum, egg, or germ is fecundated, and this is conveyed into the womb to be transformed into a living being. Such is the mode of reproduction adopted by nature for the perpetuation of mammiferæ and man, to which all hitherto stated applies, as well as that which will be mentioned in describing the development of the germ.

The womb acquires a high degree of sensibility from the moment of conception; there is a determination of blood to it, which, as in other cavities, enables it to throw out congluable lymph, to form a membrane which lines its interior and closes the orifices of the uterine tubes and mouth of the womb itself.

The impregnated ovum passes through the uterine tube against the newly-formed membrane (decidua), pushes it into the cavity of the womb, and becomes attached to it at a certain point. The germ is covered by a fine membrane of its own (amnios), and presents analogous phenomena to those we have described in the egg of the bird. The amnios contains a limpid fluid, in which the embryo swims. A spongy mass (placenta) forms between the membrane of the embryo and the womb, which transmits the blood of the parent through the navel string to the offspring. The blood is conveyed to all parts of its body, and is the cause of the growth of all.

When the fetus has acquired sufficient development, the womb contracts and expels it into the world. But this new-born being is so weak and feeble that ordinary aliments are incompatible with the delicate condition of its digestive organs. Nature finishes her work by supplying the breasts with milk, or that food which is most appropriate, and which the mother furnishes with zeal and delight. The human species often violate these sacred laws, which the Author of all things has engraved on the hearts of all the females of animals; but I shall fully comment upon this error when describing lactation.

Mammiferous animals do not engage in the act of reproduction until they are fully developed. This period is marked by an increased activity, fierceness, and unusual boldness, which is termed heat or rut, and this varies in different animals according to their size, mode of life, food, &c. Thus, it takes place at the second or third month in the mouse and other quadrupeds of this species, at the fifth or sixth month in rabbits, at the seventh or eighth in hares, about a year in dogs, a year and a half in foxes, about two years in wolves, about two years and a half or three years in mares, at the

third or fourth year in camels, at the seventh or eighth year in the stag, which we know lives a long time; and about the twelfth or fifteenth year in the elephant.

The females of animals are generally more precocious than males, and may reproduce about a year before these. It is well known to agriculturists, that the breed of cattle is very much improved by delaying reproduction until the parent animals are fully developed.

The season of heat or rut occurs at different periods of the year, and there is a fixed epoch for each species. Thus we observe it every year from November to April, in sheep; in the depth of winter in foxes and wolves, lasting about fifteen days; in October, for the same period, in roe-bucks; in autumn in bears; in January and February in cats, for fourteen or fifteen days; and from the end of March to June or July, in mares, &c. There are other animals which become in heat immediately after having suckled their young, as rabbits, hares, &c. In fine, there are some, as bears, camels, elephants, &c. that remain in heat for one or more years. Female animals are much more amorous than males. They have a viscid, bloody discharge from the vagina. This evacuation is not analogous to the menstrual discharge, during which there is no amorous desire; and the most abandoned of the female sex will object to the act of reproduction.

The season of heat excites singular phenomena in many animals, which proves the influence of love on animated beings. The most remarkable examples are stags, camels, elephants, and lions.

About the beginning of September the old stags become in heat. It commences with a kind of melancholy, which leads them to seek solitude at first; they walk with the head downwards, both day and night. In two or three days, they manifest an unusual ferocity; they attack man and all animals that come in their way. In five or six days afterwards, they pursue the hind in every direction, until they have completed the act of reproduction. The younger stags are less furious. The excess of their desires is manifested during the night, during which they fight with other animals, and sometimes receive mortal wounds. Entangled by the horns of their own species, it sometimes happens that wolves put an end to the combat by devouring them.

The rut of the old stags continues more or less for fourteen or fifteen days, and that of the young ones four or five. During this time, the hunters and dogs that attack them run the greatest danger, and often fall victims to their temerity, as these animals attack them with the fury of a lion. Both males and females exhale an odour which is so offensive to dogs, that they often refuse to pursue them.

The males are excessively ardent, and

sometimes copulate with fifteen or twenty females in succession.

Camels, which are remarkable for their fondness and docility towards their conductor, become indomitable and dangerous during the time of rut. This commences in spring, and continues for forty days, and so ferocious are these animals, that they attack lions, tigers, &c. It may be observed in this place, that the castration of males renders them timid and docile, and the flesh of those which are eatable much more delicious and easy of digestion.

Males in general are much more vigorous than females; a stag suffices twenty hinds, a bull double the number of heifers, a ram several ewes, and a stallion several mares. Thus polygamy, or one male to several females, is the established habit of this class of animals. The roebuck and whales are exceptions. They act in concert with one female in the propagation and education of their species. From the moment the female has conceived she refuses the male, and very rarely admits him, though there are examples.

Mammiferæ sometimes couple with individuals of another species, and give birth to beings of another character. Thus it is with the coupling of the horse and the ass, the ass with the mare. We know that the wolf propagates with the dog, and this last with the fox; the zebra and with the ass.

In all such kinds of reproduction it is necessary that there must not be a very great difference in organization, or they cannot take place. Thus we never see the horse produce with the heifer, the dog with the sow, &c.

The duration of pregnancy varies according to species in mammiferous animals. Thus rabbits and hares are with young for thirty or thirty-one days; cats fifty-six days; bitches sixty-three days; sheep and goats, five months; the hind eight months; the she-wolf three months and a half; the bear eight months; the fox from winter to April; the camel from one spring to another; the heifer nine months; the mare eleven months and some days; the elephants some years; the whale probably three or four years, for its offspring at birth is as large as an ox.

It is a general rule that the number of the breasts is double that of the young, but there are exceptions. The breasts are differently situated in different animals. When the term of pregnancy is completed, the females select a convenient place for themselves and their young, where they are delivered and deposit their offspring. All present their udder to their little ones, and these take the milk with avidity.

This class of animals, like insects, reptiles, birds, &c., shew the greatest maternal affection for their young. We observe it from the mouse to the large beasts in the forest, and to the sea monsters—we cannot find one female which does not bestow the greatest care and attention on her young, and which

is not disposed to defend them to death. The fever of maternal love with which she burns exalts all her faculties, supplies her strength, gives her invincible courage, and causes her to attack animals which very much surpasses her in strength. The cat will attack any dog or animal that approaches her young, no matter what be its size or strength. The bitch, at the approach of a furious wolf, does not desert her young, but remains to defend them, to combat and perish. We hear the bat, when deprived of its young, bitterly lamenting them.

Rabbits nourish their young for two successive days without searching for any aliment, and then they employ only a few minutes for this purpose. When the wolf and bear are on the point of becoming mothers they repair into the woods, select a place of safety, and defend their young with unparalleled intrepidity. In fine, these animals afford the human female the great example of maternal care and solicitude for her infant. They do not commit the physical education of their young to another, as if nature had indelibly engraven maternal tenderness upon the female heart, which no other being ever can feel or shew to offspring which is not her own.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 144.)

Enlargement of the Prostate Gland—Prostatitis.—Sir Astley Cooper, Sir B. Brodie, and others, are of opinion that enlargement of the prostate gland is caused by old age. This conclusion is, however, open to objection. Experience does not warrant this opinion, as daily observation proves to demonstration that a large proportion of aged persons are free from prostatic disease. It is very true that the disease is commonly observed in those who have indulged in profligacy and debaucheries, and who laboured under maladies of the genito-urinary organs; but a large proportion of mankind are free from such complaints. It therefore follows that prostatic disease is not an invariable concomitant of old age. Chronic prostatitis is slow, and hence it is seldom observed in young persons. The gland may be increased in size in a slight degree, but sometimes it acquires ten or fifteen times its ordinary bulk—according to Sir B. Brodie, the size of a goose's egg; to Hunter and Wickmann, the size of the fist; and to a child's head by Lloyd and Petit. Its increase in volume may occur in any part of it, and the alterations in its textures are various. It is sometimes scirrhus, at other times soft, fibrous, or cartilaginous; when incised presenting a whitish or brownish colour, and containing membranous septa. It may diminish the urethra by projecting into it, extend beyond the vesicula semi-

nales between the rectum and bladder. The eminence at the median union of the lateral lobes, erroneously denominated the third lobe by Sir E. Home, may enlarge to the size of a pullet's egg, obstruct the urethra, and project into the bladder, but it is of rare occurrence, according to Mr. Guthrie, as before stated, and seldom happens before the age of fifty. Langenbeck never found this lobe in the natural state of parts.—(Neuv. Bibl. 1818; see Bell's Surg. Observ. vol. i.) This tumour varies in size from that of a horse-bean to that of an orange, and one of the lateral lobes is often increased at the same time. At other times the enlargement of the gland converts the prostatic portion of the urethra into an irregular canal. Sir B. Brodie states that he has known the urethra to form in the gland a sinus capable of containing two or three ounces of fluid*. He also mentions that the prostatic portion of the urethra is elongated, and that there may be an increase in the length of the canal of two or three inches. The natural curve of the urethra is considerably increased. He thinks it a great mistake to apply the term scirrhus to this disease. "The chronic enlargement of the prostate may be said to be a disease of a peculiar kind, having no exact resemblance to what we meet with in any other organ. It may, however, in some respects, be compared to the chronic enlargement of the thyroid gland, known by the name of bronchocele. Like the latter, it is generally slow in its progress, and frequently, having reached a certain point, if proper treatment be employed, it remains almost stationary for many years; it has but little disposition to terminate in ulceration or abscess, and the symptoms to which it gives rise are, with few exceptions, to be referred to the influence which the disease exercises over the functions of the parts in the neighbourhood. There are but few individuals who, in the latter period of life, do not suffer some degree of inconvenience in consequence of the enlarged state of the prostate†." In some cases of this kind, the urethra is elevated towards the symphysis pubis, and this should be borne in mind in performing catheterism.

The prostate gland may be considerably enlarged without causing any unpleasant sensation, when by intemperance, exposure to cold, or gonorrhœa, retention of urine may suddenly occur, and then the real disease is accidentally discovered. In such cases the patient may be speedily relieved, and by caution, freed from another attack for a long time.

The first symptom of chronic enlargement of the prostate gland is, that the patient occupies more time than usual in evacuating the bladder, and this is generally the case

with persons advanced in life. The patient complains of dull aching sensation in the loins, extending round the hips, groins, and perinæum, and he has occasion to empty the bladder five or six times in the course of twenty-four hours, and in bad cases every hour or half hour. There is a sense of weight within the anus, as if there was a necessity to evacuate the bowels, and in some cases there are frequent erections, with slight pain extending along the urethra and the glans. These symptoms are aggravated by intemperance or sexual intercourse. In some cases this sense of aching extends along one urethra to the kidney, over the origin of the sciatic nerve. In some forms of the disease, the fæces are flattened by the pressure of the enlarged gland on the rectum. This was first noticed by J. L. Petit, but Bichat considers that the compression of the fæces by the sphincter ani will prevent it*. There may of course be enlargement of the gland, and this, projecting into the bladder, causes cystitis; and in such cases, there will be no groove on the fæces. Tenesmus, prolapsus ani, and hemorrhoids often exist. In such cases, where the disease is advanced, and the patient applies for advice on account of difficult micturition, it will be found that though he may have lately evacuated his bladder, on passing the catheter, full half a pint, or double the quantity will be withdrawn, and this will have an ammoniacal smell. We can easily account for this, when we remember that the enlarged gland may partially ascend above the orifice of the urethra, and allow the urine to accumulate behind it. The retained portion of the urine is decomposed, some of its salts fall to the bottom of the fluid, increase irritation, and form calculus. The quantity retained may amount to pints. The urine may be clear, whitish, or flocculent, or full of ropy mucus, according to the intensity of inflammation. It may be albuminous and resemble jelly. Sometimes the urine assumes a coffee colour when long retained, and gives rise to the suspicion that there is calculus in the bladder. But the history of the symptoms enables us to form an accurate diagnosis. The patient can jump, and ride on a rough road, which he could not were calculus in the bladder. According as the disease advances, there is more difficulty in voiding urine, and at length there may be partial or complete retention. This will take place if the patient retains his urine after he has a desire to pass it, when he is exposed to cold by passing from a warm apartment into the open air, or by discontinuing the use of flannel or other warm clothing in cold weather. It is stated by Sir B. Brodie, that retention from diseased prostate scarcely ever induces rup-

* Œuvres Chir. par Desault Nouv. ed. par Bichat.

ture of the bladder; while Desault considered it more dangerous than when caused by stricture, and was of opinion that a perilous extravasation speedily follows, unless relief be timely afforded. The former mentions two cases, one related to him by Mr. Travers, which terminated fatally, having been preceded by prostration of the vital powers, a brown, and black tongue, and on dissection, the vesical mucous membrane was found separated, softened, and in some points in a state of slough; coma preceded death in these cases. When the urine is much impeded, the bladder contracts powerfully to expel it; sometimes makes spasmodic efforts, forces the mucous membrane between the intermuscular spaces, and forms sacs or pouches, the same way as in bad stricture. These sacs may be small or large, and may be as many as nine or more in number; they sometimes contain pus or urinary calculi. Chronic cystitis is often the cause of death. The muscular coat of the bladder is invariably thickened, as all muscles increase in size by unusual exertion. The ureters and kidneys become finally diseased, and in some cases the ureters remain unaffected under such circumstances*. The same author states that he had known an instance in which the urine was reduced to two ounces daily, and another of total suppression, in consequence of fungosities at the vesical orifices of the ureters. In the latter, the ureters were distended with urine. A case is related, in which the kidney was so distended as to fill the whole abdomen†.

According to modern writers, abscesses may form in any part of the prostate gland, and escape by the rectum or urethra. Desault held that the coverings of the gland and the subjacent cellular tissue were most commonly the seat of abscess. Sir B. Brodie describes cases in which the abscess was between the rectum and bladder, others in which it burst into the latter, and escaped by a catheter; while Mr. Wilson has known it burst near the caput gallinaginis into the urethra‡. The abscess may point through the perinæum, and several such cases occurred to Desault, and others were successfully treated by Mr. S. Cooper.

Ulceration of the enlarged prostate sometimes happens, and may be followed by a sparing or copious hæmorrhage. Sir E. Home relates one case of the latter description, and Sir B. Brodie has met with three, in each of which the bladder was completely distended. The cause of prostatic enlargement, according to Sir A. Cooper and Sir B. Brodie, is decline of life; to Desault, gonorrhœa; to Home, constipation and excessive

venery. It appears remarkable, that decline of life should cause enlargement of the prostate, and of no other gland in the body. The other assigned causes are much more reasonable, and I believe correct. It may be caused, according to Wilson, by external injury, and occur in the chaste as well as the profligate*. It may occur in early youth, as attested by Sir A. Cooper†, and, according to many writers, long before the decline of life.

Treatment of Enlargement of the Prostate Gland.—Great diversity of opinion exists as to the treatment of this disease. The majority of British writers consider that medicine has little or no influence, and that partial relief only can be afforded by surgery. Sir Astley Cooper‡, Sir B. Brodie§, Mr. S. Cooper||, and a host of others, are of this opinion, while the French writers assert that the disease may be cured when it is caused by stricture, as soon as the primary cause is removed¶. I believe the gland can seldom be reduced to its primitive size; but I cannot assent to the doctrine of Sir B. Brodie—"the prostate of a man advanced in life cannot be rendered like that of a young man, any more than his grey hairs can be converted into black**." This position rests upon the statement which, is by no means proved, that enlarged prostate is caused by the change of the constitution in the decline of life. If the other glands of the body were proportionately enlarged by age, then we might admit the above statement as proved; and if it was not known, that the largest chronic bronchoceles, the largest hepatic, splenic, and other morbid tumours, both soft and osseous, were not curable by the internal and external use of chemical preparations of iodine and its combinations. If enlargement of the thyroid gland, of the liver, of the spleen, of the testes, of the ovary, and of the knee and ankle joints, have been reduced to their primitive size, there is no feasible reason why prostatic disease should be an exception. That all the above enlargements have yielded to iodine, is amply attested by the reports in the British and foreign periodicals, and beyond the possibility of doubt; and if iodine can act on the brain in epilepsy, as supposed and believed by Dr. Elliotson and others, and on the liver, by being rubbed on the abdominal parietes, it follows that it would act on the prostate by being rubbed on the pe-

‡ On the Urinary Organs, &c.,

rinæum, introduced in the form of suppository or injection into the rectum, and in the latter mode into the bladder. These views were proposed and maintained by Dr. Ryan in his lectures on iodine*. He also contended, that if the ioduretted remedies were introduced into the rectum, and the patient placed on his face, with the head and shoulders elevated, they would be applied to that portion of the rectum contiguous to the prostate, and, in corroboration of this assertion, he stated, that great relief was afforded to a patient under his care, at St. John's Hospital, who had been previously under the care of Mr. Key, at Guy's. The pains about the hips, loins, groins, and perinæum, were much diminished by this plan, the gland was unquestionably reduced in size, the necessity to pass urine was much less frequent, but the patient declined to submit to the treatment at the expiration of three months.

With respect to ioduretted injections into the bladder, Dr. R. observed, that he saw no valid objection to them, but many reasons for employing them. He referred to the facts established by litholrity as to the safety of frequently injecting the bladder, the inevitable contusion or laceration of its mucous coat in some cases, and, in all instances, after the operation of lithotomy, and likewise that chemical solutions, much more stimulant than iodine, had been used with impunity. He went on to mention, that the ammoniacal urine of patients affected with prostatic enlargement was in all probability much more irritating to the mucous coat of the bladder, than such a weak solution as that advised by Lugol, if employed in these cases about the middle period of life, or even later, before the bladder was injured by the urine. He argued that, by injecting the bladder with the ioduretted solution, there would be this advantage, that the fluid would be in contact with the enlarged gland, or, at least, with that portion of it which might project into the bladder. He proposed to empty the bladder with the catheter, and then inject the iodine at the temperature of 98 degrees, unless there was such irritation present, as there is in some instances, which would, of course contra-indicate its employment while such a state continued. He had seen cases, in which the bladder could not be injected with decoction of marsh mallows before the introduction of lithotritic instruments; but, on the following day, the organ retained six or eight ounces of the injection. It was his opinion that, by judicious management, the bladder might, in time, be brought to retain the ioduretted solution for several hours. He finally declared it to be his intention to carry those views into effect, but whether he has done so or not, I am unable to mention.

He also thought that, if iodine could be applied to the urethral stricture before great induration took place, it might be highly beneficial. This proposal is certainly as feasible as the nitric acid injections subsequently employed in the same disease with success by Mr. Babington, at St. George's Hospital*. I may remark, that the foregoing views appear extremely plausible, but time must determine their validity. It would be highly gratifying to the medical practitioner were prostatic disease removable by medicine. All the remedies hitherto employed, such as mercury, conium, hydrochlorate of ammonia, burnt sponge, &c. &c. have repeatedly failed.

The treatment is similar to that for acute prostatitis, with the exception of venesection, which has been already described. In addition to this plan, blisters, issues, and setons, have been tried. Mr. Hunter found suppositories of opium, with conium and sea-bathing, very beneficial in one case; the pains were diminished, and the size of the gland reduced†.

Heberden employed conium and bark, Valentine cicuta, which Sir C. Bell found useless. Fischer and Kunzmann proposed hydrochlorate of ammonia as a certain remedy, in the dose of a drachm twice a-day. This medicine failed in the hands of others. Girtanner stated that burnt sponge afforded considerable benefit. But of all remedies, mercury, with repeated catheterism, or rather the latter alone, is productive of most relief.

Prostatic enlargement has hitherto ranked among the opprobria of the healing art. It seldom fell under the notice of the physician or surgeon until it was considerably advanced, and impeded the flow of urine. Whenever partial or complete retention happened (and there is unfortunately no immunity at any period of the disease), medical aid was requested. Let us suppose a case of complete retention of urine. Most surgeons endeavour to pass a catheter, and if they fail they open a vein in the arm, apply leeches to the perinæum, or cupping on the loins, open the bowels, and order the patient to be placed in a warm bath. It sometimes happens that these measures enable the sufferer to evacuate the bladder, but they much more frequently fail. When they succeed, Sir A. Cooper thinks the following draught the best preventive of a return of the retention. *Rx.* bals. copaiiæ, liq. potasse, ãâ, *m. v.*; mist. camph. $\frac{3}{4}$ iss. But when the bladder is not relieved, then recourse must be immediately had to catheterism. The profession is divided with respect to the kind of instrument to be employed. Sir E. Hume recommended a polished elastic gum

* Lond. Med. and Surg. Journ. 1833, vol. iv.

† On the Venereal.

catheter which retained its curve, which was invented by Weiss, of the Strand. Such an instrument should be retained in the bladder until the retention is obviated, and the prostatic disease somewhat diminished. Sir E. Home condemned silver or metallic instruments, though Desault recommended them. Sir B. Brodie prefers an elastic*, and Sir A. Cooper a soft metallic instrument†, as it can be curved down before the scrotum, and a plug placed in its extremity, so that the patient may walk about and evacuate his urine whenever he has an inclination. This kind of catheter should be new, and never left in the bladder longer than a fortnight, as the urine acts upon the metal, renders it brittle, and likely to snap across.

In passing a catheter in disease of the prostate, there is no difficulty encountered until it reaches the curve made by the enlarged gland; and to obviate this, the handle of the instrument is to be slightly raised, so that the point may pass through the curved part. The handle is now to be depressed between the thighs so as to cause the point of the instrument to rise perpendicularly above the pubes. In some cases the index finger of the left hand must be passed into the rectum to guide the point of the instrument. A pressure must be made on the perinæum so as to compress the concavity of the instrument against the pubes. The greatest care is necessary in performing catheterism when the prostate is much enlarged, on account of the danger of making a false passage. It often happens that a gum elastic curved catheter with a stilette, will enter the bladder on withdrawing the latter. This is the kind of instrument most strenuously advised by Sir B. Brodie in his recent work so often quoted. He advises that the stilette should be a strong iron wire, having the curve of the silver catheter. With such a stilette, a gum catheter is as inflexible as a silver one. Sir B. Brodie also uses a gum catheter without a stilette; and should this fail with one, he advises the handle of the catheter to be kept close to the left groin. He passes the instrument as far as possible in this position, then brings the handle forwards nearly at a right angle to the pubes, and not elevating it towards the patient's navel. The handle is depressed gently and slowly between the thighs. In general the point now passes into the bladder; but sometimes this does not occur until the stilette is withdrawn, in doing which the catheter slides into the bladder. When the urethra is irritable or liable to spasms, Sir B. Brodie passes a gum catheter as far as possible, in general to the prostate, and then introduces the stilette through the instrument, which will direct its point through the prostate. This method may however fail. The

catheter should fill the urethra, and when passed into the bladder, it ought, in the majority of cases, be allowed to remain there.

When there is difficulty in passing the instrument, common sense, as well as science, shows the impropriety of withdrawing and after a short time re-introducing it. By leaving the instrument passed, the urine is not allowed to irritate the diseased prostate, and this is most favourable to the effects of remedies for its reduction, so far as this can be accomplished. Repeated introductions, or attempts for that purpose, would excite irritation, and aggravate the disease. The instrument should be withdrawn after the lapse of twelve or fifteen days, for the purpose of being replaced by another instrument. Desault has well observed that there is no rule as to the time the catheter is to be left in the bladder; when there is little difficulty experienced in passing it, there is no occasion to leave it in the bladder, but re-introduce it two or three times a day, according to the urgency of symptoms. When enlargement of the prostate with retention comes on suddenly, the patient generally regains the power of evacuating the bladder at the expiration of three or four weeks; but if the disease has come on slowly, he never regains it completely. When the prostate becomes enlarged in consequence of stricture or gonorrhœa, it will speedily yield to antiphlogistic treatment so soon as the diseases that excited it are cured*. But in cases in which catheterism cannot be performed, and when there is complete retention of urine, what is to be done? According to Sir E. Home, who gives Mr. Hunter as his authority, the catheter should be gradually forced through the prostate. The bladder of a patient so treated by these surgeons, is to be seen in the Museum of the Royal College of Surgeons. Sir B. Brodie has performed this operation successfully, and recommends it. His patient ultimately regained the power of evacuating his bladder, so as to dispense with the use of the catheter. The size of the prostate renders puncture of the bladder through the perinæum or rectum impracticable. In some cases it will be necessary to pass the catheter six or eight times in twenty-four hours, and under such circumstances the patient ought to be instructed to perform the operation himself. Every scientific surgeon is well aware that if immediate relief is not afforded when there is a desire to pass urine, the irritation of the prostate will extend to the bladder, ureters, and kidneys, cause inflammation in these parts, or predispose to the induction of urinary calculus. These diseases will be delayed, if not prevented, by leaving the catheter in the bladder, or by frequently introducing it. When

* Lectures on Diseases of Urinary Organs.

† Sir A. Cooper's Lectures on Surgery.

* Dict. abrégé des Sciences, Méd. Art. Uretrite.

the patient is able to use the instrument himself, he passes through the remainder of life with comfort, and with scarcely any suffering. When, on the other hand, the bladder becomes diseased, we must employ the ordinary remedies—hyoseyamus, camphor, alkalies, lime water, liquor potassæ or mineral acids, uva ursi,* buchü cubebs, pa-reira brava, &c. When the urine deposits an acid sediment (lithic acid), the alkalies are highly beneficial; when a white sediment (the phosphates), the acids are indispensable.

When there is ulceration of the prostate, the catheter may be left in the bladder, and opium used freely in clysters and suppositories.

Hæmorrhage may occur in such cases to an alarming extent. Sir B. Brodie describes an example in which the bladder became so much distended with blood, that it was felt as high as the navel. He bled the patient, used various astringents, but all failed, until ordered Ruspini's styptic, which succeeded. He passed a catheter into the bladder, and injected a quantity of warm water with a syringe, which dissolved a portion of the blood, and by repeating this with caution, and without exciting hæmorrhage, and continuing it for forty-eight hours, the bladder was completely emptied. The patient lived for a year and a half afterwards.

When the urine is albuminous, there is reason to conclude that there is disease of the kidney. This is the general opinion; but it has been lately stated in the Medical Society of London, by Dr. Graves and others, that this condition of urine may exist independently of nephritic disease. I believe, however, that the former opinion is often correct.

Foreign Medicine.

Microscopical Curiosities.

M. EHRENBERG, of Berlin, lately sent a collection of the above to the Institute of France, accompanied with a paper, descriptive of the best means of preserving them after study and comparison. By rapid desiccation on small plates of mica, he has succeeded in forming a collection of nearly three hundred different species of infusoria, mostly belonging to those he has already published, and to other microscopic substances. These objects are arranged on small plates, like those long used in microscopes for examining butterflies' wings, &c. He has not only preserved the form and colour of the armed rotatoria and bacillaria, but also of the softest and

most delicate rotatoria and palygastrica, those even belonging to the family and genus monades. He has preserved the tissues of plants, spermatozoæ, and cercaria, the different kinds of blood globules, together with their nucleus, the lymph, chyle, and milk globules, the nervous capillaries, &c., of a great number of animals and man. The author concludes by expressing a hope that the examination of these preparations will in future prevent any one from denying the possibility of preserving microscopical objects, the more as the difficulty of their preparation is extreme, and he calls upon other observers to do as he has done—collect and preserve—so that others may benefit by the preparations, and not take facts on mere hearsay.

Febrifuge Wine.

A. M. Blymie recommends the following formula in cases of intermittent fever, and vouches for its efficacy.

Red cinchona bark, 4 drachms.

Muriate of ammonia, 4 do.

White wine, 1 imperial quart.

Infuse during twenty-four hours; the dose is four ounces in the morning, fasting, and the same quantity at bed-time: it should be continued until the above quantity is finished, nor should the treatment be suspended on the days when there is no fever.

—*Journal de Pharmacie, September.*

Mode of extracting small pieces of Iron from the Eyes.

M. Krimer has for a long time successfully used the following means for the above purpose. He mixes twenty drops of muriatic acid into two ounces of rose-water and a drachm of mucilage, with which he bathes the eye: the muriatic acid will thus dissolve tolerably large pieces of iron. After which the eye is to be washed with milk and a cold compress kept on it for a few hours, to prevent inflammation.—*Hufeland's Journal.*

Difficult Menstruation cured by Amputation of a portion of the Cervix Uteri.

A well made woman, aged twenty years, who had experienced no previous inconvenience from her genital organs, began to complain of weight about the rectum, pains over the pubis, dragging pains of the thighs, palpitations, &c. which after continuing for

a week left her. These symptoms were evidently the *molimina menstruationis*, and they returned every three weeks, without, however, any flux of the menses. She became worse and worse, and was advised to get married; she did so, but no change for the better appeared; she experienced neither pain nor pleasure in coition. At length she was examined, when the hymen was found as high as two inches up the vagina, pierced only by a very small orifice; the os uteri was wanting; the uterus, examined per anum, and over the pubis, was found to have acquired the size of a large pear, was hard, immoveable, and very sensible to the touch. The hymen was divided. A puncture was made, and a quantity of black, syrupy blood flowed; the uterus fell in volume, and the patient was considered cured. Three weeks after, the same symptoms reappeared; the punctured point was closed, and the incisions of the hymen cicatrized. Upon this, M. Krimer resolved to take away the whole vaginal portion of the uterus, and did so two days before the expected return of the menses. Immediately after the operation there was free access for a sound to the uterus, and the menses flowed abundantly forty-eight hours afterwards. During the last nine months the female in question menstruates regularly and without pain.—*Hufeland's Journal*.

Alterations in the Milk.

M. Peligot has examined the milk of several asses, drawn under various circumstances. His conclusions are:—

When the milk is divided into portions, the first one is richer than the second, and this than the third; the difference being as much as 2 per cent. of dry matter.

Retention in the breasts impoverishes the milk, which loses from 4 per cent., or one-third of the whole solid matter.

Animals fed on carrots presented the colour of the vegetable in their milk. A strong dose of chloruret of sodium was partly appreciable in the milk, but the soluble sulphates were not so. Iodine and its preparations is perceptible in the analysis when they have been taken. Mercurial preparations have occasionally been administered to asses for the purpose of treating venereal children with their milk, but no traces of the mineral can be traced in the latter fluid.—*Journal de Chimie Medicale*.

Use of the Nasal Fossæ in the Production of the Voice.

In the Archives Generales for August is a paper by M. Valleix on the above subject, in which, after passing in review the opinions entertained by Gerdy, Malgaigne, Riche-rand, Berard, and Magendie, he comes to the following conclusions:—

1. The chief part in the propagation and modulation of the voice is performed by the larynx and mouth. The thoracic cavity evidently conduces to the reverberation of sounds. The mouth acts as a vocal aperture (*porte-voix*) that can be diminished or increased at will.

2. I would compare the nasal fossæ to a kind of reserve canal (*canal de fuite*) for the exit of the air that is not required for the buccal conduit. The air always traverses them in variable quantity, as does the expired air.

3. It is only occasionally that the nasal fossæ vibrate so as to influence the calibre of the voice; for this purpose it is requisite that there should be more air than can traverse them with ease. This effect is more readily produced in the pronunciation of the nasal words, and less so in others—hence M. Gerdy thought that air and sound only pass through the cavities of the nose from time to time.

4. When sonorous undulations are introduced into the nasal fossæ in sufficient quantity to be modified by them, the latter are to be regarded as a vocal aperture, the pavilion of which is or is not closed; their parietes then vibrate, but these vibrations have a disagreeable character, constituting snuffling (*nasonnement*).

5. If the nasal cavities are completely op-pilated, the voice has a peculiar character, that has been improperly compared to snuffling.

Remedy for Sea-Sickness.

A M. Fischer recently demanded the au-thorization of the Academie de Medicine for a remedy for sea sickness; it is composed of the seeds of one of the strychnos family and the fruit of one of the *menispermæ*, and the doses are homœopathic. The Aca-demy refused to sanction it, not because it was useless, but because the inventor would immediately make use of their name in vending it.

Preparations of Silver in Syphilis.

Professor Serres, of Montpellier, has lately been using these preparations with the happiest results, in the most old and inveterate cases of syphilis; he administers the chloruret of silver and ammonia, the oxide of silver and the metal itself in raspings. His account of the trials made with the above has been presented to the Academie de Medecine; and he promises further information on the effects of the cyanuret and ioduret of silver, of which he is at present making essay.

New Acid—Nitro-sulphic.

This acid, recently discovered by M. Pelouze, is composed of azote, sulphur, and oxygen, and is obtained by bringing into contact the deut-oxide of nitrogen and an aqueous solution of sulphate of ammonia. The salts formed by it, an account of which has been transmitted to the Academie des Sciences by the discoverer, are called nitro-sulphates; the nitro-sulphate of ammonia is that whose properties he has more particularly investigated.

Hereditary Hemorrhagic Diathesis.

On the 4th of August, Laroche, a man 41 years of age, entered la Pitié. On the right side of the abdomen he has a tumour, extending from the centre of the eleventh rib obliquely forwards to the superior iliac spine; it is six inches long, three in its broadest part, and two inches in height above the abdominal surface; the skin covering it is slightly blue, and about it are some ecchymoses. Five days before entering the hospital he had struck his side against the door key; pain and swelling ensued, the latter gradually increasing; three days after the appearance of the tumour, the debility became so great, that the patient fainted on the least exertion. The diagnosis, therefore, went to pronounce it a sanguineous tumour, situated in the abdominal parietes.

The 5th. The pulse is small and rapid; ice to the tumour; soup diet. The 6th: tumour increased; the skin over it is dark purple; the patient is too weak to speak—only answers by signs. The 7th and 8th: cold sweats, imperceptible pulse; danger imminent; ice continued. 9th: weakness

less; and from that to the 16th, his general condition and pulse improved.

On inquiry, it was found that from his childhood he had been subject to very frequent bleedings from the nose. At his twenty-fifth year the epistaxis was replaced by bleedings from the gums, which came on four times in the year, and continued for several weeks. At thirty-four the gums ceased to bleed, and hematuria supervened, and continued up to the time of his entering the hospital, for the night before he arrived he had had a copious flux of blood from the bladder. From his thirty-fourth year he had been also subject to bloody infiltration of the cellular tissue of the trunk and limbs, and twice previous to entering the hospital, he had exhibited sanguineous tumours on the abdomen. So readily does this infiltration take place in him, that in April last, a little girl having pressed her elbow on the outside of his arm, an enormous swelling appeared, and extended to the arm-pit: from all that could be gathered, it was a sanguineous one, which disappeared by rest, but left a numbness of the fingers of that hand. The slightest blows made him bleed under the skin, and he is covered with black and blue marks. From his twentieth year he had been subject to arthritic swellings and rheumatic pains, for which leeches were several times applied, but they caused frightful hemorrhage, and it was always necessary to cauterize the bites.

The parents of Laroche are still living and healthy, and though they have always led a laborious life, have never been subject to hemorrhage; but his mother, who is seventy-five years old, states that one of her uncles died of hemorrhage, but from what part she cannot say; she also recollects that one of her brothers, who was subject to bleedings from the gums, died about fifty years ago, at la Charité, in consequence of the extraction of a tooth, the bleeding from which could not be stopped: he was only seventeen years old at the time. She says that she has had eighteen children, fifteen of which died before their third year. Fourteen of these had no hemorrhage, but she cannot state by what they died—she says the blood suffocated them (*le sang les étouffés*). The fifteenth was a female, and died in the sixth week, by an hemorrhage from the vulva.

The boys grew up, and were all subject to profuse bleeding from the nose, and on the smallest prick; one of them died from croup in his ninth year. In the course of the croup, the scalp became infiltrated with blood, and caused the head to increase to an enormous size. The other, in his sixteenth year, received a blow on the calf from a cutting instrument, and whether it was that the posterior tibial and peroneal were wounded, or the capillaries only divided, the hemorrhage was so profuse, that it was judged necessary to tie the crural artery; he died at the Hôtel-Dieu, from consecutive hemorrhage. The third surviving child is the patient in the present case; he is married, and the father of three girls and a son, none of whom are possessed of their father's diathesis. It may be remarked that this diathesis was transmitted to the males alone, by the maternal side.—*Journal Hebdomadaire.*

Reviews.

Digest of the Evidence given before a Committee of the House of Commons.—Extent of Intemperance in the United Kingdom. By John Edgar, Professor of Divinity in the Royal College of Belfast. 12mo. pp. 192. London: Bagster.

THIS little work is ably condensed by Professor Edgar, and deserves an attentive perusal. It shews the immense extent to which intemperance has extended in this kingdom, and its baneful influence on society and mortality. The work is published by the British and Foreign Temperance Society, and for the charge of one shilling.

It portrays the evils of intemperance in all rank of life, but more particularly that caused by the abuse of ardent spirits. It shews, by unimpeachable evidence, the increase of crime produced by it of late years, and the numerous evils inflicted on society. Admitting all this, we cannot agree with the witnesses that ardent spirits alone are the hydra-headed monster, and that intoxication by wine or other fermented liquors is not equally injurious and demoralizing. Recommending our readers to peruse the work, we shall insert the medical evidence only, and leave them to criticize it.

“An abstract of Dr. Farre's evidence has

been already published. The following is Dr. Gordon's evidence, except the part relating to remedies:—

“2305. In your capacity as Physician to the London Hospital, has the number of diseases caused by the use of ardent spirits been the subject of your observation?—Yes, it has been particularly so.

“2306. Will you have the goodness to describe to the Committee about what proportion of the cases which come under your observation at the London Hospital are occasioned by, or connected with, the use of ardent spirits?—My attention was called to it some time ago, at the time I was assistant physician to the hospital, and was in the habit of seeing the out-patients to the amount of some thousands, probably, in the course of a year. In conversation with a friend who felt an interest in the subject, I had occasion to remark that the proportion of diseases which was distinctly referable to ardent spirits, might be 25 per cent. My friend hesitated to admit the correctness of so large an average, and in consequence I kept an account for twelve months. I need not say that the result was not a mathematical truth, but merely an approximation, and even with this reservation I am almost afraid to announce to the Committee the result—it amounted to 65 per cent. upon the whole amount of diseases, and at the same time I made every possible allowance that I could, and even struck off part, wishing to look at the subject fairly. The result was 65 per cent. upon some thousands.

“2307. When was that?—Within three or four years, and I have tried the same again and again on a smaller scale.

“2308. What is the result of your general experience?—The result of my general experience, as physician to a large hospital, is as I have stated.

“2309. Your subsequent experience is confirmatory of that remark?—My subsequent experience induces me to say a larger number. My average came to 75 per cent.; but I have stated 65, so that I might not overstep the bounds.

“2310. What classes in society did that examination extend to?—Necessarily the lower classes; but still comprehending a number of very respectable persons, such as journeymen, workmen, &c.; but generally the lower classes.

“2311. Is there any observable difference between the state of diseases produced by the habit of drinking spirits and that of drinking wine?—Yes, very great.

“2312. Will you describe what that difference is?—My belief is, that ardent spirits have a direct and specific influence upon the liver. Excess in any thing is bad; but I do not believe, as far as my observation has gone, that a very considerable quantity of wine will produce the same injurious effect as a very small quantity of ardent spirits.

"2313. Upon the liver?—I will say upon the constitution generally. When I was studying at Edinburgh, I had occasion to open a great many bodies of persons who had died of various diseases, in a population (as honourable members will bear in mind) much more renowned for sobriety and temperance than that of London; but the remarkable fact was, that in all these cases there was more or less some affection of the liver, and I account for it by the fact that these moral and religious people were in the habit of drinking a small quantity of spirits every day, say one or two glasses. They were not in any shape or form intemperate, and would have been shocked at the imputation. I had subsequently the opportunity of confirming my observation in the West Indies, where the practice prevails of taking small quantities of spirits, not at all amounting to intoxication; but in all these cases there was more or less some affection of the liver.

"2314. Has it any effect also, different from that of wine, in affecting the brain and producing insanity?—It acts distinctly on the nervous system, and produces a train of nervous diseases, to which of course insanity must be referable. There is another disease to which the use of spirits gives rise, of which the public in general have very little idea; I mean dyspepsia. The general impression is that dyspepsia is a disease of riches and luxury; whereas the truth is, that dyspepsia has become the common disease of the poorer classes, produced entirely by the practice of sipping constantly and habitually small quantities of spirits, for which so many facilities are afforded.

"2315. Will you state to the Committee your opinion as to the effect upon the constitution, of spirits taken in early life by children; has it not the effect to impede the growth, and prevent the development of the muscular powers?—Certainly, to a great degree. I have no doubt the use of spirits in children produces disorders of the nervous system, of the spine, and of the mesenteric glands.

"2316. Are not mothers, in the lower classes of life, in the habit of giving spirits to their children to keep them quiet?—I believe so. On Sunday week I was sent for into Essex, and I had occasion to pass as early in the morning as 7 A.M. along the Mile-End Road. The place was crowded, and all the gin-shops were open. In endeavouring to classify the different persons, I was horrified at the respectable appearance of many of the women and children who were coming out of the gin-shops wiping their mouths, and who had evidently been drinking; people who would not, I should imagine, from motives of decency, have gone into a public-house where they must have remained a certain time.

"2317. Is the habit of drinking ardent spirits more difficult to cure or to reclaim

than the habit of drinking wine?—Doubtless. I believe, speaking as a medical man, and as having paid some attention to the subject, that a man may confine himself to a moderate portion of beer, and a moderate allowance of wine, as daily experience shews; but I believe it is utterly impossible for a man to confine himself to a moderate quantity of spirits.

"2318. Is it because the appetite it creates requires a greater amount of stimulus to sustain it?—It is precisely like opium, or any other stimulus. When you apply to an exhausted or fatigued stomach a small proportion of stimulus, the stomach speedily requires it again, but it requires it in an increased proportion. I could mention a very remarkable instance, occurring in my own experience, as illustrative of that point. I was requested to see an individual who was supposed to be deranged; but, on visiting him, I found he had delirium tremens, a disease which is the peculiar product of drunkenness. Upon stating the fact to his family, they remarked that it was utterly impossible, for that he took two glasses of sherry at his dinner, and never tasted spirits. It afterwards appeared, upon inquiry, that the individual, who was in one of the public offices, had been frightened at the idea of cholera, and being told that brandy was the best preventive, he had, on coming to town to his office, taken a minute quantity of brandy, never taking it at home or to excess; but he so acquired the habit of taking a little every day, that he could not dispense with the stimulus. In six months he was attacked with delirium tremens, and narrowly escaped with his life.

"2319. You have stated that a person might take a large quantity of wine without prejudice, but not a small quantity of spirits? My observation was, that though excess in any thing is bad, I believe a large quantity of wine is less injurious than a small quantity of spirits.

"2320. Is there not a good deal of spirit in wine?—Yes; but it produces a very different effect in that state of combination. Probably the best answer to the question would be the well-known chemical fact, that in some of the domestic wines there is a much larger proportion of alcohol than in the foreign wines in common use, but it is in a state of combination, and produces a different effect.

"2321. Are you of opinion, that the use of ardent spirits benefits any one besides the distiller and the spirit merchant?—I should say the doctor, but nobody else.

"2322. What do you think of altogether prohibiting the distillation of ardent spirits from grain?—In a medical point of view, I wish there was no ardent spirits; of course, in a political point of view, I am incapable, from the nature of my studies, of answering the question.

"2323. Will you have the goodness to

state your opinion upon that question in a medical point of view?—Of course there are states of the system, and there are peculiar diseases, in which spirits form a part of the medicines that are used; but my employment of them, I confess, is very limited, and I do not think the loss of them would be very severely felt.

"2324. In the early part of your evidence you stated you opened more bodies whose livers were affected by the use of ardent spirits than by any other disease?—I did.

"2325. Of what class?—Generally the lower classes. Of course there would be nothing new in the observation, that a large quantity of spirits taken habitually would produce diseased liver; but my observation tended to this, that even among people of moral and religious habits, I have been struck with observing the universality of the fact, that even where they were in the habit of taking one or two glasses of spirits and water, and not drinking any thing else, disease of the liver occurred as the result. Now I have not found such to be the fact universally with respect to wine; and coupling this with other observations I have made, I think I am justified in drawing the inference that the use of spirits will lead to more chronic diseases, such as dyspepsia, than wine.

"2326. After the high duties were laid on wine, during the war, and the use of spirits increased in consequence, were not diseases of the liver more prevalent?—I should conceive that diseases of the liver are infinitely more prevalent among the lower classes now than ever they were.

"2327. And indigestion likewise?—Yes; indigestion is quite a new disease amongst the lower classes.

"2328. Do you attribute the introduction of it to the use of spirits?—Yes, I attribute it, as a physician, to the facility which the poor people possess of procuring, without loss of time, without inconvenience, and without shame, day and night, Sunday and working-day, any quantity of spirits. I was going to remark that the tenor of my evidence was this, that however horrible drunkenness is of itself, yet drunkenness produces its own peculiar diseases and effects. A man who goes into public-houses loses his time, gets drunk, and suffers miserably for it; but, as an hospital physician, I have the power of observing daily that the much smaller consumption of spirits, that habitual sipping and toping which takes place in gin-shops, produces diseases no less fatal and destructive of life.

"2329. May not the alteration of the food of the lower classes have increased the disease of dyspepsia?—The effect of drinking spirits is to destroy all desire for food; a man who drinks spirits never eats.

"2330. Does that disease extend to those who drink beer?—Not to the same extent, except perhaps among the coal-whip-

pers in the neighbourhood of London; they are paid at the public-houses, and are obliged to drink large quantities of beer, and they eat very little.

"2331. They drink a large quantity of spirits also?—Yes; but I know they drink a large quantity of beer. In the London Hospital we necessarily, from our proximity to the river, receive a great number of these individuals, and the mortality among them is frightful. The moment they are attacked with an acute disease, they are unable to bear depletion, and they die directly.

"2332. With reference to the effect you attribute to ardent spirits on the liver and other vital functions, have you any knowledge of its being adulterated, as sold in the dram-shops, with deleterious ingredients?—It would be difficult to find a more destructive poison than ardent spirits; anything that diminishes the strength of spirits would, I conceive, render them less injurious.

"2333. In your opinion is the use of ardent spirits medicinally necessary in any case?—You are aware there are many remedies of great efficacy and power which yield their active principle to spirit, and therefore, in the preparation of many tinctures and other medicines, the use of spirits is advisable. I confess that as remedial agents, I very seldom employ spirits. I will go further, and say, that in the London Hospital, where I have the most unbounded power to order brandy or wine, I use wine freely and liberally, but I never by possibility order brandy. In the case of a man who may die in two or three hours it gives a momentary fillip, but I cannot charge my memory with any medical case in which I found its use indispensable.

"2334. Is it your opinion that some practitioners use spirits more freely than necessary?—That would be quite a matter of opinion. At a consultation probably I should object to their employment, from the particular views I entertain.

"2335. As far as you know of the practice of others, you recommend spirits less frequently than other practitioners?—I have no right to say that.

"2336. Have any cases of injury to the system, by the excessive drinking of ardent spirits, in the persons of young children, been brought to the London Hospital?—They would not come under my immediate cognizance. I know that there have been instances of that kind among the poor; I have no hesitation in saying there have been cases of diseases in children produced by ardent spirits.

"2337. Children of what age?—Five or six years of age.

"2338. Is the administration of small quantities of spirits to children destructive of the mental as well as the physical powers?—Necessarily so.

"2339. You spoke of various classes of tradesmen who were brought to the London

Hospital?—The lower classes chiefly; I should hardly say tradesmen.

"2340. Journeymen in various trades?—Yes, and workmen in general. Another disease has remarkably increased within the last few years, from the perpetual habit of drinking spirits among the poor, namely, diseases of the heart.

"2341. Will you have the goodness to make any other observations that occur to you?—The whole tenor of my observations would show that, leaving drunkenness out of the question as a destructive vice and entailing its own punishment, still that practice, which is not supposed by the world in general to be injurious, namely, the frequent consumption of a small quantity of spirits, gradually increased, is as surely destructive of life as more habitual intoxication; and therefore, the gin-shops are spreading diseases and death to a degree that is frightful.

"2342. What is the effect upon the heart from drunkenness?—It diminishes the nervous power of the heart, disturbs the circulation, and gives occasion to all other diseases.

"2343. A strong opinion has been expressed by several witnesses before this Committee, that, in order to check the evil, distillation, except for the purpose of medicine or manufacture, may be altogether put a stop to; do you think such a measure practicable or desirable?—I can only answer, that provided the wants of my own profession are attended to, I can see no possible objection to it, with the peculiar feeling I entertain of the use of spirits.

"2344. There is no objection, medically or morally?—Certainly not.

"2349. Are you aware in some parts of the kingdom intoxication prevails to a great extent by means of beer alone?—I have heard so.

"2350. Where that does prevail, it is as necessary for the medical man and the moralist to guard the poor against beer as against spirits?—I should think it is; but I am bound to say that in London I have not seen the same bad effect produced from beer, and I always make the distinction that there are thousands and thousands who confine themselves to a pint or two of porter a day, but I am morally certain there will not be found in London a man who will for any time confine himself to one glass of spirits a day.

"2351. The kind of beer that is used in London is different from that which is used in the country?—Yes, it is a less acid beer, and is more wholesome.

A Manual of Pathology, containing the Symptoms, Diagnosis, and Morbid Characters of Diseases; together with an Exposition of the different Methods of Examination, applicable to Affections of the Organs contained within the Head, Chest, and Abdomen. By L. Martinet, D.M.P., Translated, with Alterations and Additions, by Jones Quain, M.D. Fourth edition, revised and enlarged. 12mo. pp. 443. London: Simpkin & Co. 1835.

THIS work has done a vast deal of good in diffusing sound pathology and diagnosis. It contains a concise view of the present state of this branch of medicine. The favourable reception it has received in this country is the best proof of the high estimation in which it is held. Many parts of it are recast, others augmented, and much new matter added to it by Professor Quain. It is a work that ought to be in the possession of every medical student and practitioner.

Though Dr. Martinet's Pathology is a complete work, it ought to be accompanied by his Therapeutics, which are also translated into our language. It may be a matter of taste to refer to the others successively, but it would be much more convenient to the reader if each section on pathology was followed by the therapeutics. We suggest this to Dr. Quain, and hope that in a subsequent edition he may act upon it. We can see no objection to his translating and augmenting Dr. Martinet's Therapeutics, though there is an English version of it before the world, and by adopting this plan he would render the principles and practice of medicine an essential service. Both works would make a moderate-sized volume, and combine subjects that are generally united.

SUPPRESSION OF QUACKERY.

Ambubaiarum collegia, pharmacopolæ,
Mendici, mimæ, Balatrones: hoc genus
omne. HORACE.

—

ONE of the most difficult questions connected with medical reform is, whether quacks, druggists, and other unqualified

persons ought to be prohibited from practising medicine. Arguing on the ground of expediency, there can be but one answer—that it is highly injurious to the community that the exercise of so difficult an art, and one requiring so extensive a range of knowledge, should be committed to individuals who, having given no proofs of their proficiency, must be presumed to be ignorant; but this question may be viewed in another light, and it may be asked, is it consistent with the free spirit of British legislation to control his Majesty's subjects in the choice of their medical attendant, or to prevent any man or woman from prescribing for another with the consent and at the desire of the latter? Considering the subject in the abstract, we conceive that the answer would be favourable to the unlicensed practitioner; but, as matters actually stand, there is a very important circumstance to be taken into account, namely, that in most instances the quack, or practising druggist, is committing a fraud upon the less informed portion of the public, by allowing himself to be confounded with the regular profession. The lower orders of people do not understand the organization of the profession; they call every body who practises medicine “a doctor” and know not any difference between the quack who assumes that title, and the graduate of an university; they call all shops which have many-coloured bottles in their windows, “doctors’ shops,” and do not distinguish the druggist from the apothecary; we should say therefore that the argument in favour of the unlicensed practitioner, derived from the freedom of the British subject, does not apply, unless it be distinctly understood that the individual in question is an unlicensed practitioner. Let him put Mr. so and so *quack* upon his door, and a strong case might be made out in his favour; however unconscientious he may be in compromising the safety of his fellow citizens for his own

advantage, and however foolish his patients may be in confiding their lives to they know not whom, we admit that it would not be easy, on ordinary legal principles, to disprove his right to practise.

But it is not thus; for the reasons above stated, every quack and practising druggist is, to a certain extent, a cheat and impostor, and, as such, ought to be prevented from trespassing on the credulity of the multitude. But, independently of all this, the common principles of legislation must always undergo some modification before they can become applicable to the affairs of a *profession*, inasmuch as every profession has some relation to society for which the ordinary laws of “the social compact” do not provide—stands in need of some protection which those laws cannot extend to it—and seems justly entitled to some particular privileges and immunities as a counterpoise to the great expense of time, money, and labour which its members must incur to fit them for functions acknowledged to be indispensable to the welfare of the community.

On the whole, therefore, we cannot see any valid objection to the legal suppression of unlicensed medical practitioners, while the benefits, both to the profession and the public, arising from such a measure, are manifold and obvious. We of course do not mean that those individuals who commenced practice as apothecaries, prior to the act of 1815, are now to be interfered with; many practitioners so circumstanced are well-informed and experienced men, and have a right to be considered as regular members of the profession; even where it is otherwise, it would be the height of injustice to send men established in a particular vocation, to seek their means of living in another, or to compel men engaged in the active exercise of their calling to pass an examination which they never expected to encounter. But if unqualified persons were *henceforth* to be debarred from

commencing practice, how great a load of poverty and misery would be removed from the profession! The public is little aware of the fact, that of the entire number of persons engaged, in one way or other, in the practice of medicine in this metropolis, a very large proportion—we should suppose not less than one half—have never passed any examination, nor gone through any regular course of education; and that many a highly talented member of the profession is starving, along with his family, while the impudent quack or uneducated druggist next door to him is in large practice. We admit that there is one position which the practising druggist may successfully occupy against us; he may ask, if druggists are not to be doctors, why are doctors allowed to be druggists? He may say, let my neighbour the surgeon-apothecary lay down his pestle, and I will cease to prescribe; *suum cuique*. Here the druggist hits us hard, and we can make no answer, but by a repetition of what we have so often urged before, that the profession never will nor can be put on a respectable footing, as long as medical practitioners dispense drugs. We do not think that this evil can be immediately eradicated, but assuredly one of the first efficient measures of medical reform must be to put things in train for the gradual abolition of this absurd and pernicious custom.

Nothing can be conceived more utterly preposterous than the present state of the medical profession in England. The profession is a farce—a bore—and every gentleman is ashamed of belonging to it. No man knows who or what he has to deal with; we are requested to meet “a brother practitioner,” and find ourselves shown up in next week’s *Lancet* for consulting with a druggist! *Proh Deum atque hominum fidem!* When is all this monstrous foolery to have an end?

Summary of Orfila’s Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot’s Manual de Médecine Légale. Translated from the French, for this Journal.

(Continued from p. 253).

Pressure—Depth of the Grave.—Pressure retards putrefaction, as Godard and some other authors have proved.

The results obtained by Godard may be estimated from the following experiment*.

On the 10th of March, at six in the evening, the thermometer standing at from 8 to 10 deg., pieces of lean veal of equal weight were immersed in equal quantities of water, but contained in vessels of different height, that of the one being two inches and a half, and that of the other three feet, including the length of a tube that was adapted to it; the smaller bottle was closed by a stopper of wax, pierced by a hole equal in size to the orifice of the tube in the other.

On the 14th, at the same hour, air was found to have been disengaged in the small bottle, but none in the other.

On the 15th, at eleven in the morning, the piece of meat in the small bottle floated, and the water was turbid; some bubbles were visible in the other, but in much smaller quantity, and the water retained its transparency.

On the 17th, at six in the evening, the number of bubbles in the small bottle was much increased, the piece of meat continued to float, while there was no change in the other.

On the 22nd, at half past seven in the morning, the water in the small bottle had a much more fetid smell, and was much more turbid than that contained in the bottom of the large one; the water in the upper part of the latter, and in the tube, had undergone no alteration. The same difference obtained in the putridity of the two pieces of meat, but they both lost their disagreeable odour when taken out of the water and exposed to the air for a few seconds. Since the meat in the small bottle was surrounded by a larger volume of water than that in the

* Godard. Dissertation sur les antiseptiques imprimée par ordre de l’Académie Paris, 1769, page 268, et suiv.

large, it might have been expected that, at the same degree of putrefaction, the water in the latter would have been more tainted than that in the former, because the putrid effluvia were less diluted; the contrary however was the case, and hence the difference in the transparency and smell of the waters, and in the putrefaction of the pieces of meat, evidently demonstrate the antiseptic power of compression.

The deeper the grave, then, other circumstances being similar, the more will putrefaction be retarded—the rather that, to the depth of several feet, the earth is cooler as it is further from the surface.

State of the Body as to Clothing.—The facts hitherto collected, and many of our own observations among others, prove that *cæteris paribus* the more immediately the bodies are in contact with the earth, the more readily they putrefy; thus a body that is buried naked, will putrefy much sooner than if it be wrapped in a winding sheet, and enclosed in a *lead* coffin; if the coffin be of *oak* an inch in thickness, putrefaction will not be so long delayed, still less if composed of the same wood only a few lines thick; and less again if the coffin be of *deal*, especially if it be very thin; finally, if the body be buried without a coffin, and merely covered with clothes, a winding sheet, or a *cerecloth*, putrefaction will take place much more rapidly. How greatly the progress of putrefaction is influenced by the envelope, is evident from the long preservation of the viscera, as compared with the skin, which is owing to the latter acting as an envelope to the former, since when the integuments are destroyed, the putrefaction of the viscera proceeds rapidly; observe also how long the brain lasts in comparison with other organs, because it has a very solid envelope in the cranium; thence it is easy to perceive the influence exerted on the process of putrefaction by clothing, and by the coffin, which act in the same way as the natural envelopes, that is, by retarding the operation of decomposing agents. A coffin, however, only delays decomposition, since every body, even when encased in lead, is finally destroyed.

Atmospheric Influences.—It will be sufficient merely to mention the influence of atmospheric heat and moisture, to convince our

readers of the effect of these elements in the acceleration of putrefaction.

After all the foregoing considerations, what are we to think of Burdach's opinion on the nature of the changes which dead bodies undergo after inhumation. According to him, this decomposition is divisible into three stages; 1. Inflation of the whole body by the development of gaseous matters; this is the period of fermentation, which lasts several months. 2. Conversion of the soft parts into a pulaceous matter of a green or deep brown colour, the body collapsing from the volatilization of its gases; this period lasts from two to three years. 3. The gases are disengaged; the fetid smell changes into a mouldy one, and there remains an earthy, fat, friable, brownish matter, which after a considerable number of years is resolved into ashes, which mingle with the common earth.

We cannot admit such notions of the progress of putrefaction in the earth; they are evidently erroneous, and calculated to lead inquirers into error.

As to the first period, have we not often, not to say always, seen bodies opened ten, fifteen, forty, or fifty days after inhumation, in a collapsed state, bearing no sort of resemblance to that of tumefaction, which Burdach supposes to continue for several months? Not that we deny that bodies ever tumefy at the commencement of putrefaction: we merely wish to establish that tumefaction does not necessarily occur; that it is frequently absent; and that, when it exists, its duration is generally not nearly so great as that assigned to it by Burdach.

With respect to the second period also, it is evident that this author has deceived himself, for, although the body collapses, it is not true that the soft parts are constantly converted into a pulaceous matter; have we not, on the contrary, observed that these parts most usually desiccate, and are reduced to lamellæ or coralliform filaments, or sometimes assume somewhat of the appearance of pasteboard? Besides, how can we admit the two or three years' duration of this period, when, in the greater part of our experiments, the bodies were almost reduced to skeletons at the end of fourteen, fifteen, or eighteen months, even when they had been buried in coffins, and enveloped in

linen? The inaccuracy of the description of the third period is likewise manifest; in truth the fatty matter which remains, in small quantity, at the last stage of putrefaction, is neither earthy nor friable, it is a sort of oleagenous substance resembling the old grease of a cart wheel deeply coloured.

In addition to all these facts, subversive of the opinion of Burdach, we may remark that, admitting the duration of the periods to have been accurately stated by him with reference to a certain soil and certain bodies, it would cease to be so with respect to other soils, and to subjects differently circumstanced. Hence, those appointed to conduct inquiries of this nature, cannot be too distrustful of such results, which, unfortunately, have been frequently taken for guides in determining the period at which the death of unknown individuals has taken place.

It is evident, then, that we must no longer accede to the opinion of those physicians and anatomists who, trusting to the report of grave diggers, believe that from three to four years are necessary for the complete destruction of the soft parts of a body under ground; others indeed maintain that this does not take place in less than six years. But are we not aware that the varieties in this particular are both numerous and extraordinary? Examples are abundant of the preservation of bodies after several years' interment; we will confine ourselves to a few. Limbrecht has left on record an observation entitled, *De manu in sepulchro ultra sæculum ab omni putredine conservata*. The same author states, that when passing by a monastery in the Narbonese Gaul, dead bodies were shown to him in a good state of preservation, which had been long removed from their sepulchres. Faber communicated to Fabricius Hildanus an observation entitled, *De cerebro non putrefacto in cadavere quinquagenis annis sub terro reposito*.

(To be continued).

ADVICE TO MEDICAL STUDENTS.

To the Editor of the London Medical and Surgical Journal.

SIR—It ought to be known to all pupils, who are about commencing their medical studies, either in London or elsewhere, that according to lately issued regulations, both of the College of Surgeons and the Apothe-

caries' Company, each course of Anatomy and Surgery must last at least six months, containing at least 140 lectures, each lecture being delivered on separate days. The course, therefore, will begin in October, and not end before the following April, or perhaps May.

Now, unless the public are clearly apprized of it, the consequence will be, that many pupils will come to town, according to the old custom, in January next, expecting then to enter upon a new course of lectures, for the study of bones and the elementary principles, when we shall be far advanced in the October course, and they will find themselves wofully disappointed and bewildered. Those, therefore, who enter to lectures this winter, should do so in October or not at all.

Your obedient servant,

G. D. DERMOTT.

15, Charlotte Street, Bloomsbury.

September 22, 1835.

Hospital Reports.

NORTH LONDON HOSPITAL.

Poisoning by Sulphuric Acid.

A MAN who had attempted to poison himself by swallowing, it is said, $\frac{3}{4}$ iv of sulphuric acid, was admitted at 12 P. M. June 24, under the care of Dr. Thomson. A surgeon in the neighbourhood had previously to his being brought to the hospital administered a quantity of magnesia. On his admission he vomited a considerable quantity of glairy, dark-coloured fluid; magnesia, carbonate of soda, and water, were administered freely, but ejected almost immediately. In about an hour the ingesta became tinged with blood, some of which was also vomited in a pure state. His pulse was 84, small and feeble. He was inclined to sleep, but could not, in consequence of being interrupted by fits of vomiting. During the night he occasionally vomited a fluid of the same character, and complained of great pain and sense of constriction in the course of the gullet. In the morning, at 7 o'clock, the pain and dysphagia were increased; for these symptoms he was bled to 18 ounces, and much relieved.

25th. Great difficulty in swallowing, with great pain in the throat; trachea and œsophagus painful on pressure, as is slightly the epigastrium; the tongue and gums whitened, the former red at the point; pulse 100; face flushed; surface hot; constant flow of saliva; breathing comfortable; 20 leeches to be applied to the throat.

26th. The pain in the throat and œsophagus much increased on swallowing, and when they are pressed on; also pain on pressing the anterior surface of the chest and the epigastrium. Pulse 104, firm; vomiting ceased; slept a few hours in the

night. Bowels confined; tongue redder, whitened surface coming off.

27th. Ordered twenty leeches to the epigastrium; half-ounce doses of castor oil every second hour, until the bowels are moved. No tenderness on pressure on the trachea, chest, or epigastrium; had a few hours' sleep last night. Bowels well opened by oil; tongue and mouth less covered by whitened cuticle; pulse 104; some pain on swallowing, as of a raw surface; vomiting occasionally; complains of a sensation of something loose in the œsophagus.

29th. Sensation of rawness and burning in the throat and œsophagus, increased on swallowing; could not sleep in the night; pulse 80, quick and compressible; tongue white at the base, red at the apex, no tenderness on pressure over the trachea or epigastrium.

July 1st. Gradually improving since last report. Discharged to day quite well.

MEDICAL BOTANY.

PLATE V.—CONVOLVULUS JALAPA.

PENTANDRIA Monogynia.—Nat. Ord. Campanaceæ, Linn. Convolvulaceæ, Juss.

Jalap is a perennial species of convolvulus, an inhabitant of Mexico and Vera Cruz, from which it was imported in 1610. The root when fresh is white and ladescent; when brought into this country, it is covered with a blackish wrinkled bark, is of a grey colour internally, and marked with darker or blackish stripes. It has a nauseous smell and taste, and when swallowed, causes a sense of heat, and a copious discharge of saliva. When powdered, it is of a yellowish grey colour.

The light, whitish, friable worm eaten pieces, ought to be rejected.

Mr. Hume, Jun., was the discoverer of *Jalapine*. He treated jalap with acetic acid, filtered the solution, precipitated it with ammonia, and obtained the jalapine by filtration. This remedy has not come into use.

Medical Use.—Jalap, in the dose of fifteen or twenty grains, is an effectual purgative, but gripes persons of a bilious temperament. It also acts slightly on the kidneys; but its extract is a powerful diuretic. The compound powder of jalap is a highly valuable hydragogue purgative, and is much used in dropsies. Even this gripes severely in some cases. The addition of some aromatic prevents this effect. Jalap is employed in costiveness, dyspepsia, mania, dropsies, and is combined with submuriate of mercury, and other purgatives of slow operation.

—o—

PEREGRINATIONS OF AN IRISH LEECH.

Our erudite and voracious contemporary the *Dublin Medical and Chemical Journal*, has for some time advertised largely the wonderful

account of the British Association, taken in short-hand by a medical gentleman? which its pages were said to contain. In order to astound us, poor matter-of-fact mortals, the learned editors, Drs. Graves and Stokes, have published a most extraordinary story of an adventurous leech, which exceeds in absurdity any thing of which we ever heard or read. Despising the meanly useful occupation to which his species are devoted, and moreover, possessing powers and organs of which they are destitute, this leech, with his sharp incisors and grinders, not having the fear of God before his eyes, did eat and burrow into the leg of a poor country damsel. He commenced his voyage of discovery at the ankle, and, piercing through tendons and muscles, and, for aught we know or have read to the contrary, through the knee joint, he winded his way, undiscovered and unfelt, without inflammation or pain, until he fairly lodged himself beneath the fascia of the thigh. He became, we suppose, overpowered by the magnitude of his undertaking, and wanting the fortitude and perseverance of a Ross, or the untiring patience of a Columbus, he resolved to return, to relate to the world the journey he had made. If he was capable of such wonders, unaided and untaught, what might have been his efforts if instructed and patronised by the learned editors of the *Dublin Journal*? Had he been of their school, he would not have stopped half way, but continued his excavations, and penetrated into the cavity of the abdomen, through the convolutions of the intestines, the liver, &c.; and may we not imagine, by some efforts of his mighty power, pierced the vertebrae, and getting into the spinal marrow, burrow on to the brain, and at length emerge from the occipital frontal fascia, or through the petrous portion of the temporal bone, thus traversing the whole extent of our mortal frame.

Our sagacious contemporary, the Green Lizard, wishing to puff off the wonderful feats of this mighty leech, and thinking that he belonged to his species (politics), without having anatomical knowledge enough to perceive the impracticability of the narrative, actually copied this leech story, which out-Herod's Munchausen's hydrophobic cloak; and the newspapers, caught by this unheard-of occurrence, have widely circulated the absurdity, of which, had they any inkling of natural history, they would have at once perceived the impossibility.

Here is the story:—

Dr. Roe, of Cavan, mentioned a curious case of this nature at the Dublin meeting. He said that he was called, some time back, to visit the daughter of a farmer residing at Drum, in the county of Cavan; the girl had been attacked several days previously with inflammation of the thigh, and at the time of his arrival was labouring under severe symptomatic fever, with delirium. The thigh was

tense, red, and shining, enlarged to nearly twice its natural size, and extremely painful. No cause could be assigned for the disease, and he was informed that until the occurrence of the present attack, she had always enjoyed excellent health. Having ascertained the existence of a collection of matter under the fascia, he made an incision, and evacuated a bowlful of pus, mixed with what he considered to be clots of blood. His attention was not directed to the contents of the abscess at that time; besides, the room was dark, and he was anxious to give vent to the pus as quickly as possible, as the patient was extremely restless. On emptying the matter from the bowl on a clean flag outside the door, the girl's mother was surprised to find among it a leech, coiled up, quite alive, and moving actively. She immediately brought the leech to him, and it continued to live for several days afterwards. On inquiring minutely into the history of the case, he found that some days before she first complained of the limb, she had been gathering water-cresses in a ditch, and had felt hurt in or about the ankle of the inflamed limb, but did not pay much attention to it at the time. On examining the ankle, he found a triangular cicatrix, such as that which might be produced by a leech bite. This fact would seem to prove that such animals can enter, burrow in, and preserve their vitality in the soft parts of the human body. A member asked whether Dr. Roe meant to state that the leech had entered in the manner supposed. Dr. Roe stated that he did not know any other way in which it could enter. The animal in question was what is called a horse-leech, and which is generally found in ditches and standing pools.

—o—

RELATION OF THE THREE KINGDOMS OF NATURE TO EACH OTHER.

WHEN we attentively consider the present condition of the inorganic kingdom, it will appear obvious, that the continuance of its existence and arrangement does not depend on the presence of organized beings. Independent of its vegetable covering, of the animals by which it is peopled, and of man himself, this globe could still revolve in its orbit, and act its part in the solar system, though naked, silent, and lifeless. Changes would, indeed, take place on its surface, in consequence of the laws of chemistry and mechanics, and independent of the aid of living bodies. The prominent parts would be worn down; the hollows would be filled up; and its outline would assume an inclination every where at right angles with the direction of gravity. These changes have, in part, been accomplished; and have impressed on the different strata the peculiar characters of their structure and superposition.

The organized kingdom, on the other

hand, could not exist alone. The beings of which it is composed may be considered as the parasites of this planet, and depend on its present movements for the exercise of their functions. Were the earth to approach nearer the sun, or recede to a greater distance, organized existence would be destroyed, by the mere change of temperature.

The presence of the inorganic kingdom is necessary to the existence both of plants and animals, as furnishing them with the elements of their composition, and a place of residence. Plants may be considered as more immediately dependent on the inorganic kingdom than animals. Their attachment to the soil is more obvious; and the changes which take place in its condition, exert a more direct influence over them. The *lichens* cover the exposed surface of the rock; and, by the retention of moisture, accelerate its decomposition. The *mosses* next establish themselves in the hollows and crevices; and, by degrees, prepare a soil for the *stamiferous* vegetables. These last attempt to establish themselves in such a manner, as to banish to the still barren districts the first fabricators of their soil. The most perfect plants are, in general, independent of the animal kingdom, or able to subsist without their presence. The members of that great family, indeed, are their enemies rather than their friends.

The animal is, in a great measure, dependent on the vegetable kingdom for food and shelter. Some animals live directly on plants, as their only nourishment, others live on the flesh of other animals, but these last are, in general, supported by vegetable food. Hence, we may assert with confidence, that if the vegetable kingdom were to perish, the extinction of life, in the more perfect animals at least, would inevitably follow. Some of the less perfect animals are more independent in their condition. The *infusoria* appear to subsist by decomposing water. They, however, prepare a suitable repast for the *annulose* and *molluscous* tribes; and these, in their turn, contribute to support the vertebral races. In both kingdoms, therefore, the smallest and most obscure species are subservient to the welfare of those which are larger and more perfect.

In viewing the relation of these great classes of beings to one another, we perceive an admirable adaptation of means, to the establishment and continuance of the present order of things. The surface of our globe exhibits a great variety of *situation* for the residence of plants. Part is occupied by land, and part is covered with water. The land varies, in composition and moisture; the water in its contents and motion; and both vary in their temperature. But however different these situations appear to be, there are plants peculiarly adapted for each, in which they flourish with the greatest vigour, and where they are only restrained within

fixed limits, by the physical characters of their station.

The condition of the earth, which thus presents different situations for the species of the vegetable kingdom, influences the species of the animal kingdom in a similar manner. But animals are not only dependent on the physical character of their station, but on the presence of those vegetables on which they subsist, whether directly or indirectly. In the existing arrangements, animals are distributed, with regard to plants, in such a manner, as that a supply of food may be readily obtained; limited, however, so as to prevent the excessive increase of any particular species. In their turn, animals influence the growth of plants, by keeping many species within due bounds, and by assisting the dissemination and nourishment of others. But amidst this variety of action and reaction, and of temporary derangement, circumstances always arise, by which irregularities are checked, losses compensated, and the balance of life preserved.

Linnaeus, from the contemplation of this subject, concluded, contrary to the generally received opinion, that animals were created on account of plants, not plants on account of animals. The defence of this opinion rests on the consideration, of animals having organs suited to cut and bruise vegetables as food, and by these operations, sometimes contributing to preserve an equal proportion among the species; and on the following reasoning—that the iron was not made for the hammer, but the hammer for the iron—the ground not for the plough, but the plough for the ground—the meadow not for the scythe, but the scythe for the meadow. The exclusive consideration of the indirect consequences of the actions of animals, has obviously betrayed Linnaeus into this opinion. That it is erroneous, may be easily demonstrated, by the employment of his own method of reasoning. Plants, we know, are furnished with roots to penetrate the soil for nourishment and support; and fishes have fins adapted for swimming. Now, if the soil was not made for plants, but plants for the soil; if the sea was not made for fish, but fish for the sea, then, instead of considering animals as created on account of plants, we must draw the mortifying conclusion, that both animals and vegetables were created on account of inorganic matter; the living for the sake of the dead.

All that we know with certainty on the subject, amounts to this—that the organized kingdom is dependent on the inorganic; that animals are greatly dependent on vegetables, and that the different tribes in each kingdom have determinate mutual relations. Judging from the mode of action peculiar to the species of each kingdom, we are led to conclude, that vegetables

are superior in the scale of being to minerals; that animals are superior plants; and that they constitute a harmonious whole, in which the marks of power, wisdom, and goodness, are every where conspicuous.”

—o—

MANUAL OF OPERATIVE MEDICINE, BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

4. *Of Phlebotomy.—From the Arm.*—The *Surgical Anatomy of the Parts.*—Ordinarily we find at the bend of the arm five principal veins which may be operated upon by the lancet; these are, taking them from without inwards, the radial, the median cephalic, the median basilic, the common median, resulting from the union of the two, and the cubital or ulnar. But, with respect to their number, size, and depth, there are a crowd of anomalies.

The median basilic is generally the largest, the most superficial, and the most constant. It runs along the tendon of the biceps and the brachial artery, from which it is separated by fibrous or cellular laminae. Sometimes it passes parallel to the artery and immediately above it (he means in front of it). More frequently the vein crosses the artery very obliquely. It is surrounded by several filaments of the internal cutaneous nerve. Its vicinage to the artery renders bleeding in this vein very dangerous; but it is the one most commonly opened.

The other veins do not present any such danger, but they are more or less surrounded with nervous filaments which are most numerous towards the inside of the arm. Lesfrances prefers the upper parts of the median cephalic, since he finds no nervous filaments around it there; if its lower portion be preferred, the hand should be placed in a state of pronation. Next, he approves of the radial; next, the common median, remarking, however, that when this is in the space which separates the supinator longus from the pronator teres, it is surrounded by nervous threads, the section of which is unavoidable; and, in thin subjects, the radial artery is so near as to be in danger. Of the remaining veins, he prefers the median cephalic to the cubital, this being so closely surrounded with nerves; the lower the former vein is opened, the safer is the operation, as the artery becomes more deeply seated as it descends the arm. The greater part of the dangers resulting from the relative position of the artery may be avoided by placing the arm in a state of forcible pronation.

In operating we employ a lancet, shaped at its point like the outline of a grain of wheat; all other shapes are obsolete. In bandaging the arm we employ a tape, which should be tied in a bow sufficiently tight to prevent the return of blood through the superficial veins, but not constricted so much as to interrupt the circulation in the arteries. If not ambidexterous we may bleed in the left arm with the right hand, observing to stand on the outside of the limb. In introducing a lancet, we should first be careful to fix the vein firmly with the thumb, to prevent it from rolling, to puncture the skin, in an almost perpendicular direction, about a finger's breadth from your thumb, and to bring out the instrument in the direction of a gradual curve, which is to be larger or smaller in proportion as we wish to make the orifice greater or less. When we wish to bleed repeatedly from the same orifice, we may usually effect our purpose by removing the bandage and reapplying it above the orifice, at the same time rubbing the arm upwards in the course of the vein. Some destroy the recent adhesions by a blunt-pointed probe, but we may in this way produce phlebitis.

When a vein does not appear, the arm may be tied up for half an hour or an hour, and the muscles moved about; there is no objection to bleeding over an old cicatrix.

It is denominated a *white bleeding* when the vessel is not opened. In this case, if the vein should appear at the bottom of the incision, we may attack it again with the lancet; if not, another vein must be sought after. After the flow of blood has commenced, it may suddenly stop from various causes—from the ligature being too tight; when this must be loosened—or from its being too lax, when it must be made tighter—or from the orifice being too small, in which case this will require enlarging—or from a little portion of fatty substance projecting through the wound, and which may be pushed on one side, or cut away with the scissors—or from the openings in the vein and skin not being parallel, which is often the case, it being the common practice to open the vein with the arm in a supine position, and to draw off the blood with the arm pronated. Lastly, fainting prevents the continued flow of the blood. This may be obviated by stopping the vein for a short time by pressure with the thumb, administering restoratives, and placing the patient in a recumbent posture; after which the bleeding may be resumed.

The ecchymosis which follows bleeding, may be removed by enlarging the opening in the skin, and keeping a bandage and compresses on the part for a few days. The serious accidents which may follow bleeding, are a wound of the artery, consecutive

phlebitis, pricking the leader or aponeuroses; the last, however, is at the present day regarded as unimportant. When the artery is wounded, the hemorrhage may be stopped by bending and pronating the fore-arm forcibly, and applying a piece of money over an ordinary compress.

Bleeding in the Foot.—The internal saphena vein may be opened in front of the inner ankle, or the external saphena vein in front of the outer ankle; but the latter is seldom large enough to be punctured when we cannot succeed with the internal vein.

The patient should sit some time with the feet in warm water; then the surgeon having made choice of one of them, ties a bandage about two fingers' breadth above the ankle, takes the foot out of the water, receives it on a napkin placed over his knee, and opens the vein, taking care not to penetrate so far as the bone, lest he might break the point of his lancet, and leave it in the wound. When the blood spirts freely forth it is received in a basin in the usual manner; when it merely drips, the foot must be replaced in the water, and we are obliged to form conjectures as to the quantity lost, by the colour of the water. The foot should not be plunged too deeply in the water, for fear the pressure of the column of fluid should restrain the bleeding; and it should be sponged often, and the toes moved about. A figure-of-8 bandage is placed round the foot and ankle when the bleeding is deemed sufficient.

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF MEDICINE, EDINBURGH; SESSION 1834-5.

LECTURE XXXI.

Exhaustion of Irritability—Death.

WHAT has preceded appertains chiefly to certain more or less permanent changes in the degree of irritability, arising from causes which, from being slow and progressive in their operation, give rise to no secondary effects. But an important consequence of the fact lately laid down as an axiom remains to be mentioned with reference to such changes in the degree of irritability as are brought about suddenly. In this case, upon the irritability being diminished by excessive irritation, the part subsequently, of course owing to one of the conditions of its actions having been lessened, undergoes diminished irritation from the usual stimuli; but as diminished irritation is, according to the same axiom, a cause of increased irritability—although, when the process is slow, the effect is imperceptible—the part in this case afterwards, owing to this condition of its action having been now increased, undergoes increased irritation from the same stimuli, and its action is thus poised, as it were, on either side of the line of health, till the healthy action is at length restored. And if this line of action be thus set up by a primary diminution of irritability as the result of excessive irritation, it must be equally established by a primary increase of irritability as the result of defective irritation, the only difference consisting in this, that the second link in the first chain of actions corresponds to the first or third links in the second, and so on for the rest. Hence it follows, as a corollary from this axiom, but more especially with reference to what may be called acute cases, that *a precisely similar state of either excessive or defective irritation may result equally from the operation of two agents the primary action of which is diametrically opposite*, and that either a stimulant or a sedative application (a) may

(a) Whether there be any agents upon the body, except such as are negative, like cold, want of food, and so forth, which operate directly in diminishing irritation, is more than doubtful. It is indeed a leading tenet of the modern Italian school, of Rassi, Tommasini, Borda, and the rest, that there do exist agents, which they distinguish by the names of contra-stimulants or negative-stimulants, the operation of which is *immediately* to lower irritation, and of this nature is the celebrated tartar-emetic in its effect upon the action of the heart. It seems, however, reasonable to believe that the effect of the operation of every positive agent on irritability must be irritation—since all that we understand by irritability is the property of being called into action by all kinds of agents applied to it. Irritation is indeed susceptible of diminution

in either of two ways—by the abstraction of stimuli, by which one of its conditions, or by that of irritability, by which the other is to a greater or less degree withdrawn; but, while the former is easily effected by the employment of negative agents, we know of no means of effecting the latter except by exciting preternatural irritation, and it is in all probability in this way that all the reputed contra-stimulants produce their effect. It is true, the sedative effects of their agents on certain organs are frequently much greater than appear to be explicable upon the presumption that they are merely the consequences of the previous excitement of these organs; but there is a source of fallacy here of which it is of importance to be aware. If tartar-emetic, for example, first violently excited the action of the heart, we should imagine that we had no

appear to give rise to either the one or the other exclusively according as this or that stage of its action is the more prolonged. It is thus only that we are enabled to solve the apparently difficult problem how not only heat and cold, *Boreæ penetrabile frigus adurat*, but excess and deficiency of food, a superabundance of blood, and too great depletion, and numerous other opposite causes, should give rise often to precisely the same effects. It will be obvious that all the positive agents increase directly one condition of excessive irritation—namely, the stimulus in action, while all the negative increase indirectly the other—namely, the susceptibility acted on; but both equally occasion increased irritation, and its consequence diminished irritation, in which inflammation—the head and front of the great majority of diseases to which the body is liable—consists. The same principles are adapted further to explain the nature of what is commonly called the latent stage of inflammation, which stage is in fact the most active stage of any, consisting as it does in that state of preternatural irritation of the capillary vessels which is preparatory to the diminished irritation in which the disease essentially consists. It gives rise, it is true, of itself, to no particular symptoms, and it is by those alone which take place during the subsequent stage—which is perhaps always the longer and more violent the longer and more intense has been this alleged latent stage—that we at length recognise the disease; but it is not on that account the less active. Nor is there any difficulty in understanding upon these principles how the same agents—positive or negative—for example, heat or cold—which are often instrumental in producing inflammation, should be so frequently among the most effectual means of removing it. Indeed, if the above doctrines are well founded, it could not have been otherwise; for since these agents produce the disease only by the collapse which follows the inordinate irritation which they occasion, the one directly and the other indirectly, it would necessarily follow that a renewal of this irritation, not beyond, but only up to the natural point, must alleviate or remove it. Hence the benefit derived in inflammatory diseases in general, after the abstraction, if necessary, of a part of the load to be moved forwards by the capillary vessels of every agent which operates in exciting the moving powers; and such agents we accordingly apply either directly to the part affected, if it be one which admits of this, or sympathetically, if it be one which does not: and it is in the latter way that all the reputedly revulsive remedies are of advantage in such diseases—not by counter-irritating, as is sometimes so vaguely supposed, or withdrawing irritation from a part already undergoing too little—but by communicating to it a stimulus by which that irritation is to the requisite degree increased (*a*). It might further have been expected that the particular stimulus would be found most competent to effect this end which had already, by its deleterious action upon the part when in a state of health, proved its adaptation to the specific irritability of this part; and it is upon this principle that the whole doctrine of the homœopathia—ignorant as they are, for the most part, the patrons of this doctrine, of the fundamental truth on which they are proceeding—essentially hinges. But the subject of the mode of action of the causes and remedies of diseases, however connected it may be with that of increased and diminished irritation, is almost an inexhaustible one; and its full consideration belongs rather to pathology and therapeutics than to elementary physiology. It may be repeated here, however, in conclusion of this subject for the present, that as it is of some change in that irritability or susceptibility which when natural is the *predisposing cause*, as it were, of health, whether of the whole body or of certain organs, and whether acquired in the manner recently de-

difficulty in understanding how this action should be afterwards in an equal degree diminished; but, on entering a little into the subject, we should find that we could explain it only on the presumption of some deleterious change having been effected in its nervous matter by the preponderance of absorption as the *indirect* result of this irritation of its muscular tissue. But why may there not exist substances capable of increasing *directly* this action of the absorbing vessels, and thus of diminishing the proper action of the heart without having previously increased it? It needs not perhaps be always *through* an irritation of tissues capable of displaying any sensible action that a stimulus takes effect upon their absorbents; and if it operate on the latter directly, we can have no measure of its primary stimulating action, involving as it does only the molecular process, and can recog-

nise it only by its secondary and sedative effects, upon processes obvious to the senses. Perhaps had we any criterion of the former, we should find that the latter always in fact accurately correspond with it.

(*a*) If any two subjects had to be selected, among those which are most frequently in the mouths of medical men, upon which they are, generally speaking, the most totally destitute of the faintest outline of the shadow of an intelligible idea, we could not perhaps do better than pitch upon the two last alluded to—the nature of the latent stage of a disease, and the operation of a so-called revulsive remedy. It would be flattery to call the opinions commonly entertained on these subjects erroneous—they have no pretensions for the most part to the name of opinions at all. The subject will be resumed in its proper place.

scribed, or natural to a certain age, sex, temperament, idiosyncrasy, or habit of body, that every predisposing cause of disease consists, so it is to some change in those salutary powers by which irritability is excited, and which when natural are the *exciting causes* of health, or to some other powers which are altogether accidental and deleterious, that every exciting cause of disease is referable; the *proximate cause* of disease in the mean time bearing the same relation to the two that a healthy function bears at once to irritability in its natural degree, and to those powers by which it is naturally called into action.

As life and irritation are virtually synonymous terms, it follows that the total cessation of irritation must constitute death; but as this cessation may arise from a failure either of irritability, which is irrecoverable, or of the requisite stimuli, which may be restored, it results that death may be either permanent or temporary, the latter constituting what is commonly called suspended animation, or more vaguely, when general, asphyxia, syncope, or prolonged apoplexy, in which, although there is no life or irritation, there still remains a susceptibility of it (*a*). Permanent death may be either of a certain part alone, or of the whole body. When it is only of a certain part, it constitutes what is called mortification or gangrene, which is of two kinds, dry and humid—the former arising from a mechanical obstruction of the larger blood-vessels of the affected part (*b*), so that the renewal by the capillaries of the proper ganglionic nervous tissue—still presuming this to be the immediate seat of irritability or vitality—in proportion to its consumption, is impossible; the latter, from such a degree of that diminution of the irritation of these capillaries, in which inflammation consists (*c*), as, instead of favouring, is incompatible with secretion, so that the same effects result. When the death is of the whole body, it may be presumed to result from a similar deterioration taking place in the ganglionic nervous tissue in every part; in other words, from each part becoming disorganized—for, if irritability or vitality is the result of organism, as has been from the first assumed, this is a necessary inference—by the secreting process falling short in every part of the absorbing, in consequence of the excessive irritation either of every part directly, or of some one part, which by sympathy involves all the rest. Such a total exhaustion of irritability or vitality is sometimes very suddenly effected, as when death is occasioned by electricity, by violent exercise, by an intense emotion of the mind, by certain poisons, or by a blow on the head; all which circumstances have been already stated as preventing, as well the natural coagulation of the blood, as the usual rigidity of the muscles, owing probably, the former to a defective decomposition of the blood, and the latter to a deterioration of the muscular tissue. But besides these phenomena, which seem to be susceptible of a purely chemical explanation, the muscles after death, under these circumstances, do not contract under the strongest known stimuli; which can arise only from a sudden failure of that property which, under the ordinary circumstances of death, is only very gradually abstracted from them. In the latter case the irritability or vitality appears to fail first, as already observed, in those organs which have the smallest and fewest ganglionic nerves, and the parenchyma of which is soonest deprived of its blood, and to be retained for the longest time in those the nerves of which are the largest and most numerous, and the parenchyma of which retains its blood the most tenaciously. It seems to be exhausted accordingly, among the larger muscles of man, first in the left ventricle of the heart, the nerves of which are few and small, while its contractions are so forcible as very rapidly to expel most of the blood from its parenchyma. This organ generally ceases to obey the strongest stimulus in about half an hour; and the irritability ceases afterwards successively in the muscular coat of the large intestines, in that of the small intestines, in that of the urinary bladder, in the right ventricle of the heart, in the voluntary muscles in general, in the muscular coat of the gullet, in the left ventricle of the heart, and lastly in the left auricle, the nerves of which are numerous and large, while its contractions are so feeble as to allow of a great accumulation of blood in its parenchyma, so that this organ sometimes retains its irritability for eight or nine hours (*d*). Now even the shortest of these periods, it may be observed, is much

(*a*) It will be observed that death is here spoken of merely in relation to failure of the two conditions of life—irritability and the stimuli by which it is excited—quite abstractedly, and without any reference to the exciting cause of the cessation of the individual functions, which could not of course be entered into before these functions had been severally and collectively discussed.

(*b*) Dodart, Noel, Lange, Bouchet, Hodgson, &c.

(*c*) "Mortification," says John Hunter, "is the most simple effect of debility;" and

according to Dr. Thomson, "the two morbid states (that is mortification and inflammation) may in some measure be regarded as stages or periods of the *same disease*"—facts which are of themselves a sufficient refutation of the opinions of those who, while they allow that mortification consists in a total cessation, or the greatest possible diminution of irritation, still assert that inflammation, which is the *same morbid state*, consists in an increase of it.

(*d*) This very nearly corresponds with the results of the experiments of Nysten, which have been already alluded to. It appears

longer than the blood, when drawn from the body, takes to coagulate—consequently, it might at first sight appear that to attribute the longer or shorter retention of the irritability or vitality of the several parts, under these circumstances, to the continuance in them of any function to which this fluid is instrumental, must be erroneous; but we are not to imagine that the process of the coagulation of the blood in its vessels begins at the period from which we are accustomed to date death. There can be no question but that the irritability or vitality of the parenchymatous tissue, with its oscillating and often retrograde currents of blood, very long survives, as has been elsewhere stated, that of any of the larger muscles—probably from its preserving the integrity of its own ganglionic matter much longer than that of the same matter as interwoven with the other tissues—and that long after the sensible motions in which respiration, circulation, and so forth consist, have ceased, the molecular actions, in which secretion and absorption consist, and those by which the coagulation of the blood is prevented, continue to be performed (a). It has been pretty well established that the hair and nails continue to grow, that the perspiration sometimes appears, and that the tears not unfrequently flow for some time after apparent death, and that a person who at the time when respiration and circulation ceased had an anasarcal tumour, is often buried without it; and if the vital processes of secretion and absorption (b) thus continue in the parenchyma so near the surface of the body, from which the blood is comparatively so soon withdrawn, how much more will this be the case in the internal parts in which it is in the same degree accumulated (c). It appears, therefore, perfectly reasonable to presume, that as in cases of sudden death, produced by any one of the agents lately enumerated, the process of secretion instantly so far falls short of that of absorption as at once to deteriorate the ganglionic nervous matter—and it has been already presumed that it is by a similar deterioration of the proper muscular tissues, under these circumstances, that the ordinary rigidity of the muscles is prevented from taking place—so in ordinary cases the former process only gradually succumbs to the latter, and that it continues the longer in every part, according as the conditions, at all times favourable to secretion, are the better maintained. But absorption is a vital process; and as it is by absorption that that degree of disorganization on which the failure of irritability or vitality depends, is directly effected, it is obvious that, not only is to die as characteristic of organized beings as to live, but, as elsewhere remarked, it is from a distinct vital process that death in all cases immediately results. It may be alleged indeed—to omit the mere truism that if a being had not lived, it could not die—that it is not because absorption continues, but because deposition does not, that vitality fails; therefore, that the process is not a positive, but a negative one. This, however, is not the case; for when both simultaneously cease, as occurs in suspended animation, vitality is not destroyed; consequently, when it is so, it must be attributed to that process which is continued to the exclusion of the other, and must be regarded, therefore, as an active and positive, and not as a positive and negative one. We owe our organization originally to a vital process—that of secretion, when there was no corresponding absorption; we owe the perfection of our organism likewise to vital processes, those of secretion and absorption, the former somewhat preponderating over the latter; we owe the maintenance of our organism to the same vital pro-

from the observations of Bicker, Sir Anthony Carlisle, and others, that some chemical agents applied to muscles after apparent death have the power of retarding, while others have that of accelerating this exhaustion of their irritability. The action of these substances, however, is, in all probability, not chemical—since such an action upon muscles is perhaps incompatible with any retention of irritability—but strictly vital, the former class of substances perhaps tending to diminish, the latter to increase that preponderance of absorption over secretion—processes still going on in the parenchyma of the muscles—on which the ultimate failure of this property appears to depend.

(a) That the motion of the fluids in the parenchyma is in a great measure independent of the action of the heart, was shown long ago by Spallanzani, who has been abundantly supported lately by Marshall Hall and Wedemeyer. We know likewise that at first the two had no connexion with

each other.

(b) In adopting this opinion, we must take care not to confound exudation and imbibition with secretion and absorption. The two former are merely physical processes, and perhaps never take place—notwithstanding some recent experiments by Fodère, Magendie, and others, which seem to prove the contrary—through living tissues; the two latter are strictly vital processes, and certainly never happen after irritability is exhausted.

(c) That this is the case is obvious from the remarkable fact, that while the marks of an inflammation of the surface, such as erysipelas or ophthalmia, frequently entirely disappear soon after death, those of an inflammation of an internal organ are in general manifest till decomposition ensues—nay, not unfrequently even healthy internal parts acquire after death a pseudo-inflammatory appearance, as noticed long ago in particular by Dr. Yelloly.

cesses, the two being now precisely balanced; we owe the decay of our organism still to these vital processes, but now absorption somewhat preponderates over secretion; and, we owe the destruction of our organism also to a vital process, that of absorption, when there is no corresponding secretion (a). When we die temporarily, we merely cease to live; but we cannot die permanently otherwise than from the destruction of our vitality, which can be destroyed only simultaneously with our organism. The last vital process implies, it is true, the possession still of vitality; but it is one which actively destroys the structure whence results the property on which itself depended, and all is afterwards the repose of inorganic matter. And that such is the case is rendered probable, among many other things, by the long retention of their vitality by the sluggish water-plants, and by cold-blooded and torpid animals in general. The difficulty with which reptiles are deprived of vitality is well-known, and fishes in general retain the same property very tenaciously. The heart of the eel, for example, will palpitate for thirty or forty hours after having been removed from the body; and it is upon the long and forcible contractions which the muscles of the carp undergo after apparent death, that the practice of crimping them depends. It is very remarkable, also, that the retention of their irritability is very much increased in those mammals which hibernate during their hibernation; the heart of a hedge-hog which has been destroyed during this state sometimes continuing to beat for ten hours after apparent death (b). But had the cessation of vitality been effected by a negative, and not by a positive process, those beings should surely have been the first, and not the last, to display it, in which the vital processes are most languid. Such as were slow to live, should have been quick to die; but as it is, the less energetic the other manifestations of life, the less rapid the destruction of vitality. The "function of death" partakes only of the inactivity of the functions in general.

But irritation, and therefore strictly speaking, life, may cease from the failure, not of irritability, but of some of the stimuli by which it is naturally excited, and thus give rise to temporary death, otherwise called suspended animation; or, when general, asphyxia, syncope, or prolonged apoplexy (c). Temporary death, also, like permanent death, may be either of certain parts alone, or of the whole body. Of the former we have examples in the effects of cold, or the abstraction of heat, on certain parts of living animals, as the ear of a rabbit, which, after having been frozen, frequently resumes its vital actions on the re-application of heat; and of the latter in those of the same negative agent on leeches, perch, and many other animals, which are often conveyed in a congealed state for many miles, and still return to life on being thawed; as well as, in a minor degree, on all those which hibernate, such as the pupæ of many insects, most reptiles, among birds the cuckoo and perhaps the swallow; and among quadrupeds the dormouse, the marmot, the bat, the hedge-hog, and many others, the animation of all which is in the winter to a greater or less degree suspended. The same thing occurs to terrestrial animals in general, from an abstraction of air, as by hanging or drowning; to aquatic animals, and to some not aquatic,

(a) A beautiful illustration of the proximate cause, if we may so express it, of death, might be drawn, were this the place for doing so, from the phenomena of death from sheer old age, in which every dry, shrunk, and opaque tissue betrays this preponderance of absorption over secretion, and every faculty, irritable, sensitive, and rational, manifests the effects of it. Not all the soaking in the cauldron of Medea, nor sleeping with fair Shunamites, nor drinking potable gold, nor replenishing the veins with all the young blood in the world, can ever enable man to resist his own inherent causes of decay till he shall find out the secret of controlling the process of absorption. Till this be done, "vain are the hopes of men," as observed by Dr. Symonds, "who look for an agerasia."

(b) Dr. Marshall Hall, *Phil. Trans.* 1833.

(c) These three morbid conditions of the body are very frequently confounded together; and indeed the names *Ἀσφυξία*, *ἄσφυγμία*, *λειποθυμία*, *ἀποφύξια*, *λειποφία*, κ. λ. τ., which have been applied almost indiscriminately to them all, seem to imply that the symptoms are almost indistinguishable.

The difference, however, consists in this, that in asphyxia the exciting cause, whatever it be, takes effect first on the lungs, the suspended function of which involves very rapidly those of the heart and brain; in syncope the exciting cause takes effect first on the heart, the suspended function of which extends instantly to those of the lungs and brain; while in apoplexy the exciting cause takes effect first on the brain, and it is not till after an interval more or less prolonged—since, immediately necessary as are the organic functions to the animal, the animal are not equally so to the organic—that its suspended function involves those of the lungs and heart. Thus hanging, drowning, negatively deleterious gases, &c., produce asphyxia, abstractions of blood, the long-continued erect posture, and so forth, produce syncope, and a deficient conveyance of the stimulus of sympathy, produces that extreme degree of apoplexy which involves at length the organic functions; but in all, when fully established, the symptoms are the same, with whatever organ they may have respectively begun.

as the garden snail, from an abstraction of water, and to all, in a greater or less degree, from an abstraction of their blood; to plants again, and the seeds of plants, from an abstraction of soil and moisture; and, in short, to every form of organized being, from an abstraction of any stimulus requisite to its natural irritation. Some of these negative agents produce merely, when their operation is temporary, a primarily diminished and a secondary increased degree of irritation, as already explained; but when it is permanent, they do not merely diminish irritation, and thus, by destroying the balance between certain vital processes, effect certain changes of structure and consequent changes of property, and resulting action, but they obstruct irritation altogether, and thus by suspending in an equal degree every vital process, put a stop to life, without impairing vitality. The only wonder is the length of time that this state of ambiguous existence, this retention of organism and of *l'aptitude à vivre*, without *la vie*, sometimes lasts (a); but the wonder ceases

(a) The instances of an obstinate retention of irritability by man are much less remarkable than those by some other tribes of organized beings; but still not a few well-known melancholy cases of premature interment sufficiently testify its occasional occurrence after apparent death from natural disease, and it is still more common in suspended animation from the ordinary causes. It is said by Winslow that the Emperor Zeno, upon his tomb being opened some time after burial, was found to have devoured a part of his arm, and the same thing is reported to have happened in the case of the celebrated Duns Scotus. The great anatomist Vesalius is well known to have been persecuted by the Inquisition for having opened the body of a Spanish nobleman, who upon the first incision betrayed signs of life; and it is said by Grainger, in his Biographical Dictionary, that the Earl of Pembroke, who died in 1630, upon being opened for the purpose of being embalmed, raised his hand. A lady also, who died in Herefordshire, is represented in the Reports of the Humane Society for 1787, to have been restored to life after interment, by the attempt of a thief to steal a valuable ring from her finger, and numerous similar cases are on record by Diemerbroeck, De Hilden, and many others, sufficient to teach us great caution in pronouncing any person irrecoverably dead before indications of actual decomposition have occurred. With respect to suspended animation from cold, it is said by Guaguin that in some countries man is a hibernating animal, and that there is a people of Muscovy who die every year on the 27th of November, and are not restored to life till the 24th of April following! But whatever we may think of this, the instances of a pertinacious retention of irritability by man after hanging and drowning—exclusive of those cases of preservation from the effects of the former, owing to nature having furnished the culprit, apparently in anticipation of such an accident, with an osseous trachea—are innumerable. Among the best accredited instances of recovery from suspended animation produced by hanging, are those of Ann Greene, who was executed at Oxford in 1650, and of Margaret Dickenson, who suffered in Edinburgh in 1727, both of whom were restored after a considerable interval; and resuscitation from

the effects of drowning is possible, according to Currie, after half an hour from the supervention of asphyxia, according to Pechlin, after eighteen hours, according to Willis, after twenty hours, according to Kunckel, after eight days, and, according to Brumann, after seven weeks: the greater part of all this, it is hardly necessary to say, is fabulous. But examples of a long retention of irritability become more and more remarkable as we descend in the scale of creation, and some recorded cases of it in quite the lowest tribes of organized beings are almost incredible. Various species of tremella for example, a kind of fungus, display this faculty to a very great degree, the tremella nostoc having been looked upon in former times as a prodigy, from its appearing frequently, immediately after heavy rains, in places where during the longest drought no traces of it had been perceptible, and other species often suddenly covering ditches after a shower with beautiful verdure which had for weeks or months before presented the appearance only of dry colourless hairs. But it is manifested even still more strikingly by some of the lowest animals, and in particular by the microscopic wheel-animal (*Rotiferi*, 1), which, as noticed by Leeuwenhoek, Barker, Spallanzani, and others, after remaining for three or four years in the form of ash-rivelled point, which may be broken in pieces with a needle like a crystal of salt, is still recoverable by a drop of water; and by the eel of blighted corn (*Vibrio*, 1), which retains the faculty of being resuscitated, as asserted by Ginnani and Needham, for twenty or thirty years. It is worthy of remark, that in all these animals this property is destroyed by electricity, seeming quite sufficiently to show in what it consists. But the most wonderful instances of obstinate retention of irritability are met with in the seeds of plants, which sometimes remain for many centuries buried in the bowels of the earth, and still, on being thrown up into a congenial soil, spring into life; and it is said that some which were taken not long ago from the hand of a mummy found in one of the pyramids, and which must have been immured between two and three thousand years, produced unknown plants when sowed in one of our botanic gardens!

when we recur to the fact that organized tissues are in their chemical nature entirely sui generis, and held together by vital affinities—not composed of sodo-albumen, gelatin, and so forth, and held together by common chemical attraction; and that till this takes place, which is not till they have become disorganized and their irritability or vitality has deserted them, they are unsuceptible of the usual chemical decomposition. But their vitality cannot desert them otherwise than by a vital process; so that there seems to be no cause why the duration of these tissues should not be as perpetual as that of inorganic matters—and in fact the supervention of permanent death and consequent chemical decomposition in these cases appears to imply at least a momentary and partial return of irritation, for which perhaps it is more difficult to account than for the persistence of their repose. That such, however, really takes place when temporary terminates in permanent death, is more than probable. Innumerable causes may give rise to this return of irritation, in as far as regards the molecular processes, which alone are concerned in effecting that disorganization on which the destruction of irritability depends, but which of course gives rise to no perceptible phenomena; and there is every reason to believe that as these molecular actions long survive the sensible actions, when both are failing from the cessation of irritability or vitality, so these will be the first to be restored upon any stimulus again taking effect upon the system in cases of suspended animation. The slightest returning irritation, confined thus to the parenchyma, is now excessive, and of course establishes and maintains a balance of action in favour of absorption over deposition, tending to disorganization and the destruction of vitality; and it is only upon such stimuli taking effect more generally upon the system and restoring the action of the lungs and heart, so that a portion of fresh blood is sent into the parenchyma—while the very diminution of vitality which has already taken place there, is now a cause of diminished irritation, and consequently of a regeneration of irritable matter and a re-accumulation of irritability—that recovery can take place. It is well known how precarious is, in every instance, the health for a long time after restoration from suspended animation, if it have been of any considerable duration, and how great the liability to inflammation, hemorrhages, and so forth, as is commonly said from the violence of the re-action. This is a sufficient proof how severe a shock, even in these fortunate cases, the irritability has sustained, and how narrow has been the line by which a return to health was separated from permanent and irrecoverable death. The process from which either might have resulted was the same, differing only in degree; and, had only one link of the chain of functions in which life consists been re-established, it would have been that which constitutes “the function of death”—the last to be maintained in the former case, the first to be restored in this.

Upon this at length occurring—at the instant of a total cessation of its irritability or vitality—all that an organized being had possessed as characteristic of its composition ceases also; and, that power by which its elements had been previously united into a living whole giving way to common chemical affinity, there result now as its really proximate principles, sodo-albumen, gelatin, fibrin, and all the others commonly so reputed, such having been previously the association of these elements in each organ, as to give rise after death to the development in each of these principles in definite proportions. But such principles are not long stationary. According to laws which have been elsewhere explained, they become more or less rapidly decomposed; and what was man, in common with the lowest worm—that “noble piece of work—the beauty of the world, the paragon of animals”—becomes at length a loathsome mass, useful only in ministering to the nourishment of still organized beings, in return for having, in the pride of his organism, appropriated the disorganized remains of so many similar beings to his own.

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

Dispensary, Gerrard Street, Soho:*

Session 1834-35.

LECTURE XLIX.

Vices of Conformation, and Intra-uterine Diseases of the Liver, Spleen, Pancreas, Mesentery and Peritoneum—Intra-uterine Peritonitis and Ascites.

GENTLEMEN—I have now to direct your attention to the vices of conformation, and

intra-uterine diseases of the liver, spleen, pancreas, mesentery, and peritoneum, as organs connected with the digestive apparatus.

Diseases of the Liver.—The liver, intended to fulfil one of the principal functions in the phenomena of the intra-uterine life, in transmitting to the fœtus all the blood which is brought to it from the mother, presents nevertheless very few pathological lesions, notwithstanding the importance of its functions.

One of the alterations which is most frequently met with in the liver of the fœtus, and even in that of adults, is the presence of tubercles in the tissue of this organ; but we are ignorant to what cause to attribute the development of these bodies, which

have been observed, not only in the liver of the human fœtus, but likewise in that of many other animals. M. Husson*, in making an autopsic examination, at the Hôtel Dieu, on the body of an infant which lived only 8 days, found soft tubercles in the liver, which had already commenced suppuration; MM. Dupuy and Andral, jun., have met with similar tubercles, the first in the liver of a lamb, the second, in that of a young rabbit; the tissue of the organ, with the exception of these tubercles, was perfectly healthy.

Morgagni (*De Sedibus et Causis Morborum*, lib. iii, epist. xlviii, art. 55), relates a case of an infant, which when brought into the world had a tumour of the size of the fist, having no skin on it, on the abdomen towards the right side and a little above the umbilicus, which terminated all round by a border a little elevated, and appearing to form a cicatrix: it was uneven, livid, and yielded to pressure, as if it had been formed by an intestinal mass. The infant did not at first evacuate its alvine dejections, nor did it take the breast, but in a few days it did both the one and the other: the dejections were green and strongly marked with lines; the tumour became more livid, gangrenous, and the part of the right muscles situated under it was the seat of abscess: the infant died on the 35th day. At the autopsy were found two livers, one was small, divided into deep lobes, and situated in the ordinary place; the other much larger, shapeless, united to the first by a thick intermediate membrane, and annexed to the trunk of the vena porta, surrounded in the vena cava under the other liver, extended to the peritoneum, to which it adhered and formed the tumour already mentioned. There was no trace of the gall-bladder. The absence of the last organ has been often observed, without any influence on digestion; and in such cases the hepatic ducts opened directly into the duodenum.

In acephalous infants the liver may be absent; and it is occasionally transposed, or placed external to the abdomen, or even in the thorax. This organ sometimes presents deep furrows and other alterations. Intra-uterine vices of conformation are however of comparatively rare occurrence.

Congenital diseases of the liver are sometimes observed during intrauterine life. These are sanguineous congestions, small tuberculous granulations, such as are frequently and simultaneously discovered in the spleen and lungs. Passive congestions of the liver are the most frequent lesion of this organ in new-born infants, and this is easily explained by the fact that the hepatic is under the direct influence of the general circulation, and will then consequently cause

disorders of it. The least disorder of the general circulation will give rise to passive congestions of the liver. These are very common to new-born and young infants, in whom the liver is large often descending to the crest of the ilium or hip-bone, being also extremely vascular; and it is for this reason that we occasionally observe the convex surface of the organ covered with a sanguineous exudation which assumes the appearance of a layer of blood. M. Billard has seen in several cases an effusion of blood into the cavity of the abdomen, the result of this turgescence. He states that the symptoms of hepatic congestion were not peculiar or well marked, but were similar to those of pulmonic congestion. Thus, in asphyxia of new-born infants, there is nothing more common than to find the liver gorged with black and fluid blood, as well as all the large abdominal vessels, and those of the circulatory apparatus. Hepatic and splenic congestions are caused by a determination of blood to the abdominal organs, on account of the vascularity of the liver and spleen. This fact is illustrated by the congestions of the liver, spleen, lungs and brain, caused by the determination of blood from the surface of the body to the deep-seated vascular organs during the cold fit of ague, and more especially when that disease is of long duration. Congestions of the infantile liver are often accompanied by an abundant biliary secretion, and the gall-bladder has been found distended with thick bile, sometimes green, or sanguinolent. (Billard.) The treatment of hepatic is the same as of intestinal and thoracic congestion, which has been already described. The indication is to equalise the circulation of the blood, as the vessels in the great cavities are intimately connected as branches of the same circulatory trunk.

Inflammation of the liver can scarcely be detected in infants, even when there is fever with pain on pressing the organ. M. Billard, who perhaps paid more attention to infantile pathology than any other author, failed to discover hepatitis during life. He made researches on fifty infants of both sexes, from one day to six and eight months old. In twelve in whom the liver appeared to be healthy, he found the colour of the bile altered in two; it was abundant and clear in three; very green in one; blackish and very copious in two, and a yellowish green and very viscid in two. It therefore appears that though the liver is sound, the colour and consistence of the bile are very variable.

He also observed that the bile may vary much in the same pathological state of the liver. In some the liver was highly congested, in others remarkably pale. In these and other morbid states, the bile was yellow, green, black, and sometimes viscid and colourless. In some cases the liver exhaled the odour of sulphuretted hydrogen.

* Communications orales faites à l'Académie de Médecine, séance du 16 avril, 1825.

He concluded from all his observations, that the appearances of the liver are very variable, that those of the bile are not less so, and that it is impossible to establish positive relations between the state of the bile in its reservoirs and the normal and pathological state of the liver. He candidly confesses his incapacity to explain the modifications of the biliary secretion.

He next enumerates the result of his observations on the state of the liver and the qualities of the bile in relation to the intestinal dejections. He adds that he examined forty-eight infants for the purpose of determining this point. These suffered from enteritis or gastro-enteritis; he observed twenty affected with diarrhœa accompanied by very copious yellowish dejections; and twenty-six with equally copious green dejections. The liver was scarcely injected in fifteen of these infants; in four of these the bile was slightly abundant and very clear; it was green and very abundant in three; and presented nothing remarkable in the rest. The liver was gorged with blood in twenty-five; the colour of the bile varied from a pale yellow to a green; and in one case the gall-bladder instead of containing bile, was filled with a great quantity of black blood. In the last eight cases, the liver was yellow, green, and brown; and the bile was fluid and clear in some, while it was thick and green in others.

It follows then from the results of these forty-eight cases, that the liver presented different appearances; it was sometimes sound, sometimes injected, and presented anatomical characters, which the actual state of our knowledge does not warrant us to ascribe to that class of diseases which nature demonstrated. We cannot attribute the disorder of the digestive canal to the liver, or the yellowish and greenish evacuations to an alteration of the bile. M. Billard is of opinion that such evacuations in diarrhœa are caused by enteritis, and he censures both the British and American authors, who advise purgatives, emetics, and stimulants in such a state of the intestinal canal. He contends that former erroneous ideas must vanish before the light of pathological anatomy. Experience and multiplied observation have convinced him that diarrhœa is caused by enteritis, and not the result of diseases of the liver, and that the exhibition of purgatives to expel the supposed irritating bile from the intestines is a gross error. There are however few, if any scientific British practitioners who exhibit purgatives in diarrhœa; though it must be admitted that it is too much the fashion to refer all diseases of the digestive canal in adults to the liver, and to prescribe blue pill (*pil. hydrargyri*) as the best remedy. Nevertheless experience in many thousand cases of infants during the last twenty years has convinced me, that when the alvine de-

jections are brown, green, black, white &c., mercurial alteratives combined with mild aperients are almost invariably successful.

Some authors have concluded, that disease of the liver and duodenum are often concomitant. MM. Cruveilheir and Denis have observed ramollissement of the duodenum in infants, accompanied by a morbid paleness of the liver. M. Billard, has further observed various diseases of the liver in duodenitis.

Congenital jaundice is occasionally observed, and of this I have given an account on a former occasion. Three cases of absence of the gall-bladder are described by M. Denis. In other examples, the organ is irregularly developed; and in some new-born infants it was found inflamed. (Billard).

The biliary ducts have been found contracted, obliterated, and inflamed; but more frequently in adults and aged persons than in infants.

The spleen has been found congested, ruptured, and inflamed in new-born infants.

The pancreas may be diseased in new-born and young infants. This organ is largely developed at birth, for assisting digestion; and M. Billard inquires whether the abundance of serous motions in one form of diarrhœa may not be produced by the secretion of the pancreas. The mesentery has been rarely found diseased in the fœtus. M. Desormeaux has however stated that Cehler has found the mesenteric glands indurated, adipiform, and scrofulous, not only in the fœtus of strumous parents, but in those whose mothers presented no trace of scrofula.

In diseases of the liver, spleen, pancreas, and mesentery, a judicious employment of mercury and iodine will in the majority of cases of engorgement and chronic enlargement effect a cure. Alterative doses of calomel or hydrargyrum, c. creta, and of hydriodate of potass or other preparations of iodine, with the external employment of these remedies, will in general be efficient. But pathology proves to us the incurability of many morbid conditions of glandular and other organs*.

Besides these anomalies in the abdominal organs, which often cause death, either before, or a short time after birth, the fœtus may be affected with the different inflammations of the digestive organs which are observed in the adult. M. Desormeaux treated an infant a few years since, whose mother had been in good health during pregnancy, and which, when brought into the world was extremely thin, the whole surface of the body being of a yellowish white colour, with the countenance expressive of pain. The abdomen was swollen,

* For the use of these remedies consult my edition of Hooper's Physician's Vade Mecum, 1833; and Formulary of Hospitals, 1835.

hard, and pained by pressure; intestinal circuvolutions were manifest through the integuments; all announced the presence of chronic *enteritis*. It was confided to the care of a nurse; and notwithstanding its excessive weakness, it at first survived on some drops of milk, and then sucked the breast. It ultimately became a fine healthy child.

M. Denis (*Recherches d'Anatomie et de Physiologie Pathologiques sur Plusieurs Maladies de Nouveau-nés*, p. 129) has seen a great number of new born infants die on the second or third day after birth, from gastro-enteritis, which had clearly appeared to have been of long standing. In an infant of the male sex, which died immediately after birth, he found the lungs imperfectly expanded by air, the flesh soft, infiltrated, and the skin red; the stomach presented superficial ramollissement, with lively injection of its mucous membrane; that of the small intestines was also injected, and covered with a layer of creamy exudation. Contraction existed near the cæcum; the large intestines were filled with meconium.

The other organs contained in the abdomen of the fœtus are, as well as those of the adult, susceptible of being affected with divers inflammations. M. Véron (*Sur quelques Alterations Organiques Observées chez les Nouveau-nés*, *Nouv. Biblioth. Med.* July, 1825, p. 301) has related a case of manifest peritonitis, existing in a fœtus which was well-formed, but which did not live more than twelve or fifteen hours after birth. An effusion of purulent serosity in the peritoneal cavity, with an albuminous layer of one or two lines of thickness, adhering to the internal surface of the serous membrane, which was of an intense red colour, was detected. All the intestines and other abdominal organs were adherent, and formed one mass.

Congenital peritonitis has been also observed by M. Billard. He states that in the bodies of two infants, one died eighteen and the other twenty-four hours after birth, he detected chronic and very solid adhesions between the different convolutions of the intestines; and in one the convex surface of the liver adhered by four very solid though fine filaments to the anterior wall of the abdomen. One of the infants was emaciated, very small and pale; the other presented the ordinary appearances of newborn infants.

A similar case is related by M. Dugès. On opening the body of an infant, born at the seventh month and a half, at the *Maternité*, he found all the abdominal viscera agglutinated by a firm yellow albumen. There were thin, false membranes on the liver, spleen, bladder, &c.; the epiploon adhered to the intestines; these were yellow, hard, and thickened; they appeared to be mixed with concrete albumen; they contained a

yellow frothy mucus, &c.* Three cases, nearly similar, are related by M. Billard. He also describes acute peritonitis, which he thinks must have occurred in the last days of pregnancy, or during parturition. He does not attempt to account for the cause of the disease, and asks, is it possible that such diseases can be transmitted from the mother to the infant? He narrates a few cases of acute and chronic peritonitis after birth.

The symptoms are tension of the abdomen, which is prominent about the navel, restlessness, pain indicated by the countenance and reiterated cries; vomiting, eructations, constipation, great debility, smallness of the pulse, difficult respiration, cold extremities, which are speedily followed by death, unless proper means are employed.

The diagnosis between this disease and enteritis is not easily drawn, nor will the constipation in the one or diarrhœa in the other establish it. The treatment is, however, the same. Peritonitis may be distinguished from spasm or colic by the periodicity of pain in the one, and its continuance in the other.

The prognosis is generally unfavourable.

Treatment.—The infant ought to be removed from the breast, a leech or two applied to the abdomen, the warm bath and fomentations employed, and the bowels opened with two or three grains of calomel, followed by castor oil, infusion of senna, &c. if necessary.

When convalescence is established, the infant should be fed with ass's, cow's, or goat's milk, its abdomen swathed with flannel over its chemise, and its lower extremities kept warm, especially in cold weather. It is also essential to keep the body warm, as there is a strong sympathy between the skin and the abdominal, and all deep-seated organs, both in health and in disease.

Ascites.—According to modern pathology, and to the preceding facts, it follows that infants may be attacked, both before and after birth, with ascites or abdominal dropsy. A determination of blood to serous membranes, such as the peritoneum and pleura, may cause congestion or inflammation, and the effusion of serum often follows, forming ascites and hydrothorax. Dropsy is a rare disease in infants before the termination of the first year of their age; but it may be intra-uterine, two cases of which I detailed on a former occasion, which were described by MM. Roux and Ollivier. The infants, as at a later period of life, were pale, feeble, and affected with œdematous swellings of the lower extremities.

The different forms of dropsy very frequently supervene after scarlatina, more es-

* *Recherches sur les Maladies les plus importantes et le moins connues des Enfants nouveau-nés.* Paris, 1821.

pecially in cold weather, and there is disease of the liver, heart, kidneys, spleen, or any large tumour pressing on the vessels of the abdomen.

The usual *treatment* of the disease in adults, adapting it to the age and constitution of the patient, is usually successful, unless in cases of visceral disease.

The different forms of herniæ and prolapsus recti which belong to abdominal diseases, have been described under the head of displacement and protrusion of parts.

By JAMES MANBY GULLY, M.D.

LECTURE XVI.

Internal Inflammations.

THE order in which I propose to treat of internal inflammations is as follows:—

1. We will examine them in the apparatus of assimilation, or digestive canal, beginning from the pharynx, where we have already examined them, then passing to the appendical organs of the canal, the liver, the pancreas, and the spleen. It is of importance that we should commence in this way, because the gastro-intestinal phlegmasiæ are the most common, and no internal disease can be treated without acting on the digestive canal. Strictly speaking, it is possible to do without such action on the tube in external inflammations, provided they can be got under; but when it is a matter of internal phlegmasia, a knowledge of those of the stomach and intestines is absolutely necessary, first, to prevent their being confounded with others, and next, in order to avoid exasperating them involuntarily or innocently, as many persons do.

2. After the inflammations of the assimilative apparatus we will pass to those of the depurative apparatus of the kidneys and bladder, then to those of the internal genital apparatus, on account of the proximity of the organs. I think it would be an embarrassing process, and would expose us to repetitions, were we to pass from the abdomen to the chest, and then back again to the abdomen. It is a point of importance to be fully acquainted with the propagation of inflammation in one splachnic cavity previous to passing to another; on this account, after studying this phenomenon in the particular organs of the pelvis, we shall examine it in the tissues common to all the viscera, in the cellular and the serous tissues.

3. Thence we shall pass to the apparatus of respiration, starting from the larynx, where also we have seen inflammation.

4. Then come that of the circulation, in which it will be interesting to view the inflammations in their secondary, after considering them in their primitive point. Here we shall establish a division between the inflammations of the centre of the apparatus and those of its prolongations.

5. The nervous apparatus will be placed the last. We shall then behold inflammation in the nervous centre and extremities, as far as it is possible to distinguish them from the tissues in which they are mixed up, forming a very important question; for veritable phlegmasiæ, involving the nerves of a capillary tissue, are daily put forward as neuroses, whereas they are not confined to the nerves.

Such is the plan we propose to follow. The importance of the inflammations of the assimilative apparatus, with which we are first of all to be engaged, will be felt by you in the exhibition we are about to make of them.

Gastro-intestinal Inflammations. — We speak of the inflammation of the mucous or villo-mucous surface of the intestinal canal; the muscular and cellular tissues entering into its composition may participate in this inflammation, but are rarely the primary seat of it; moreover their inflammations are far from evident, are too circumscribed, and exert too little influence over the functions in general to be clearly diagnosed. In order to get at a diagnosis of limited internal inflammations, or such as are situated in tissues of a small degree of vitality, an immense habit in pathology and pathological anatomy is for the most necessary, and is only obtained by repeated observations, comparisons, and deductions, and after becoming familiar with the numerous symptoms exhibited by the numberless shades of inflammation.

The causes of the inflammations of the internal membrane of the digestive canal are exceedingly numerous. In passing them in review it will be necessary to place them in an order that allows of their easy recollection, and we will found this order on the materials of hygiene. I habitually begin with those that are connected with the functions of the organ, and observe how far its exercise or action may conduce to the morbid condition: it is a physiological mode of proceeding. Thus we place the *ingesta* into the digestive tube in the first list, omitting, for the present, those which exert a specific and poisonous action; of these we shall speak in a separate section, and meantime confine ourselves to the most common, the most numerous, and the most avoidable causes.

To live we must of necessity be brought into contact with a certain number of agents whose action we cannot avoid, and which we ought to know how to manage; of this kind are aliment and drink. In these the causes of inflammation are too often conveyed in the shape of condiments, sauces, fatty substances, &c., which all excite the stomach to inordinate action. Some indi-

viduals support this kind of alimentation, but others cannot, and in them inflammation appears. Instinct informs us, by the feeling of thirst, of the explosion that threatens, and we prevent it by the use of cold drinks, lemonades, ice, and other refined correctors; in this manner we neutralize the superexciting causes of the digestive organs as far as may be, but not always successfully. In the first list, therefore, of the causes of intestinal phlegmasiæ, we place too stimulating alimentation; were we to confine ourselves to what is essentially nutritive, fecula, gelatine, albumen, fibrin, milk, &c., all nutritious, without the aid of stimulants, we should be far less subject to those of phlegmasiæ; but people have created these sources of pleasure, and they hold by them. On the other hand, nature herself has united to nutritive substances of the animal and vegetable kingdoms, particular extractive principles: to meats ozmazome and salts: to plants, bitter, aromatic, and acrid principles: all the cruciferous and umbelliferous plants contain an irritating principle, exhibited in alliaceous vegetables, radishes, cress, celery, &c. These must be eschewed if we would avoid a gastritis: you will perhaps say that I am anticipating on therapeia—yet not so; I am only throwing light on the etiology of inflammation of the digestive canal, and I prove that direct and purely alimentary stimulation, may engender gastritis and enteritis. If you doubt this I will quote rubefacients to you; mustard, for instance, the phlogosing effects of which are, I think, sufficiently evident in the form of sinapism applied to the skin, and which therefore may readily be supposed to produce terrible internal inflammations. But this is not all: if you escape the immediate effect of all these ingesta, and you assimilate them without their having inflamed the organs in which they are deposited, the great quantity of blood they furnish engenders plethora, especially if the exercise is not proportioned to the consumption of them. You then carry within yourself a general and ever-attractive stimulant, that powerfully seconds the external stimulants that still form your food. Natural hemorrhages may be established, and be necessary to free you from the overfulness of the vessels, and to maintain health in an equilibrium; but should they be suppressed, here is a fresh reason why inflammation should take possession of the organs.

The materia medica also exhibits a train of substances which you take or prescribe with the best intentions, but which may produce the diseases now under consideration. Of this kind are tonics properly so called, which more or less resemble the condiments that are added by nature to nutritious substances; generally speaking, aromatic, hot, burning substances that cause a flow of saliva, astringents, actual sudorifics, even purgatives, are capable of inducing gastro-enteritis, especially if an inflammatory predisposition exists.

True some saline purgatives allay inflammations, but this is only when they have been reduced to a certain point; otherwise they only add to the excitation and make it pass into inflammation.

Nor must we forget the cerebral innervations, and let us call things by their right names. I might speak to ye vaguely of the passions, moral affections and intellectual labour; but I would be precise with, and materialize these causes. Are you convinced of their enormous influence? Do you not believe that when we study assiduously, when we are affected by strong passions and violent emotions, that the brain is strongly excited thereby? This excitation of the intracranial nervous apparatus never stands alone: it radiates through the nervous system, and everywhere causes disturbance; it quickens the heart's movements, injects with blood the mucous surface of the viscera, of the stomach as well as the lungs, and particularly of the duodenum; it even acts lower down in the trunk, and frequently after moral affections the fæces are expelled more forcibly, and the urine driven out copiously. The latter, it is true, does not always depend on a sanguineous injection, but on an impulse communicated to the muscles of hollow organs; but do not imagine the brain acts only on these muscles; so much does it act on the capillary system that persons under its influence may be attacked with hemoptysis, hæmatemesis, apoplexy, &c., and that those labouring under depressing moral affections, may suffer from jaundice and disturbed movements of the secretory organs, or from bilious vomiting, especially if they be highly susceptible individuals. Robust men who have never known sickness, have no right to judge of others by themselves; I have known physicians, men that were always in excellent health, laugh at me when I told them that it was possible for the digestive canal to become inflamed from a moral cause—stupid jesting! whether strong or out of health we ought, if we would profit by observation, to put ourselves out of the question, and not consider our own persons as the limit of all the facts that may be laid down; in medicine as well as in metaphysics, the neglect of this principle has led to a host of errors.

You may very well imagine that if a man is predisposed to inflammation, no very great influence is requisite to make him the subject of a phlegmasia. Take a convalescent that has been freely bled and kept to low diet, who is even beginning to support some stimulation, and put him into a fit of passion; you will see that nothing more is required to hurry him into a worse condition than he was before, and to give him a violent gastro-enteritis. Subject him to another kind of violent emotion and the same may happen. But enough on moral causes. They more particularly influence pre-disposed individuals, in pretty nearly the same manner as the suppression

of the hemorrhages does. If you happen to be more disposed to convulsions than to phlegmasiæ, these causes will determine convulsions: if the brain maintains a confusion, a state of irritation, insanity may be the consequence; here, however, we consider these influences as they are capable of producing phlegmasia of the digestive apparatus.

In the etiology of these affections, after the excess or aberration of innervation, I place the action of the *circumfusa*, and of these, that of the atmospheric is the most prominent. I would not venture to lay stress on this course, so evident is it, were it not that it has been called into question by certain sceptics, who love to doubt even the most staring facts, and who not having paid the attention to the causes of disease that we have done, are at the pains of rejecting every thing they cannot conceive of. Whatever such may affirm, the atmosphere is capable of producing inflammations of the mucous membrane of the digestive canal in two principal ways, by cold and by heat; and first by cold, which is the most frequent cause of them: there can be no doubt that the considerable diminution of the circulation of the fluids, which takes place in the exterior of the body when we turn cold, produces visceral congestions; but herein we must distinguish the general impulse from the particular effect it is capable of producing, and which varies according to the predisposition. If it acts on an individual provided with stanch gastric organs, but who has a delicate pulmonary mucous surface, it will produce a bronchial catarrh; if it acts on another whose digestive tube is more sensible, there it will concentrate its effects. In this way I first of all point out these facts in a comprehensive manner, before entering on the details: thus I have proceeded during the twenty years that I have been observing them in the hospitals. Thus also is it that the phrenologists proceed: they first describe the most prominent cerebral organs, and for that purpose they choose persons whose tendencies are the most decided, and their acts most characteristic; they then go on to establish their judgment, and describe the moral dispositions beneath the degree from which they stand.

I suppose it to be the end of the summer or of a mild autumn, in which no extraordinary cause has appeared. Both heat and cold being wanting, you see scarcely any diseases; but as soon as the weather becomes cool, we see abundance of gastro-enteritis: they are the first affections that are seen. Should the weather become warm again, they disappear and return once more with the cold. If you interrogate a great number of sick persons, you will most frequently find that they became so from this cause, which came upon them when in a state of inaction. Cold is the enemy of life; you endeavour to resist it by clothing, by food, exercise, occupations, and passions that re-

quire activity: but you cannot always be in breath, you must repose; then it is that cold seizes on you, and you may there and then fall sick, even without any predisposition, unless you have taken precautions. This is particularly remarkable in armies, after battles and forced marches that have exhausted the powers, when repose is sought for under the open sky; the same also will be observed in young recruits on whom sorrow is preying, and who are obliged to keep watch through the night instead of sleeping, as was their wont after the day's labour; after their night patrol, they lie down on ill-aired or badly covered beds, and sleep under the influence of cold; or if they are of the guard, they pass suddenly from a well-warmed guard-house into a cold air, &c. Those who have brought some money from home with them, think to mitigate their troubles and stifle their sorrows by liquors, of which they take in excess; and cold, sorrow, and excess, from the robust youths they were, make them sickly.

By thus observing the causes of diseases in masses of men subjected to one particular mode of life, a much better idea of their production is obtained than by confining ourselves to isolated cases. Add to this, that if the regimen of these men is changed, a predisposition in them is the consequence. Thus youths of the lower orders who quit the country to come to Paris and exercise inferior callings, such as water carriers, errand runners, &c. by which they hope to ameliorate their condition or support life, fall sick after a time; is it by a particular and specific influence? Not at all; these individuals are in the same plight as the conscripts referred to; true it is not by means of a faction that, with shouldered gun, they suffer the effects of cold; but it is by means of a station at a street corner, or post, by the avidity of gain that keeps them with wet feet near a fountain waiting their turn to draw water, by the parsimony that makes them ill lodged, ill clothed, and ill fed, with aliment that requires stimulating liquors to force the stomach to digest it. Both these classes of men, recruits, and labouring people of the town, are subject to similar influences to cold and unnatural stimulation of the digestion; and in both gastro-enteritis may be the result.

Among the *applicata* and the *gesta*, you may also find most powerful causes. Certain callings in the performance of which the abdomen is compressed, render liable to inflammations of the organs contained therein. Inordinate and permanent constrictions, such as those from women's corsets, occasion irritations of the abdomen, and make the wearers subject to obstinate disorders. Contusions of the same part, especially when there exists a predisposition, induce phlegmasia in it, of which the following is an instance. A young man had been cured of an intermittent fever by cinchona, but his belly remained hard, tense, and somewhat tender when he

was walking; some irritation certainly remained, though in other respects he considered himself very well; he chanced to fall, was carried to an hospital, and the following day was seized with a violent enteritis with threatening peritonitis, an effect that was owing to the shock received by his body, already in a predisposed state. Some men refuse to admit of such a thing as irritation; but what will you make of those exaltations of sensibility that manifest themselves in a thousand ways, and frequently for next to nothing, if you do not recognise shades in which these affections that are lower than inflammation can be ranged? How, without it, can you understand predisposition? Would you wait until the general disorder that is to be the consequence of it, manifests itself and proves the reality of its existence? In that case you cannot be beforehand with the mischief, and your want of foresight will scarcely be combined with the talent that is requisite to treat it properly after you have allowed it to form. Examine life, therefore, in all its modifications, and health in its smallest derangements, in order that you may ascertain when it is only still tottering; irritation is your best guide.

Blows, falls, wounds, every thing requiring surgical operations, come under the head of *applicata*. In traumatic fevers, what happens when external violence has been applied to our organs? An effusion of blood, a congestion of first serous, then sanguineous fluids and after all, inflammation, which comes on the more rapidly as the previous predisposition has been strong. Sanguineous congestion itself without wound or violence is a powerful cause of inflammation, though a less palpable one; it may take place without preliminary irritation, but determines it in tissues that are not accustomed to it, and they then quickly fall into the inflammatory state. Brown omitted an important truth when he said the blood was the primary stimulant of the organs, and that when accumulated in them to excess it gives them an inflammatory tendency; it is true he expressed this proposition in an abstract manner and without connecting it with the living tissues, but it is not the less valuable. When blood is retained in an internal apparatus in consequence of certain circumstances, a phlegmasia may be the result; these circumstances are a plethora, an excessive irritability of the heart, a vivid degree of excitation, the suppression of the menses in women, of hemorrhoids in man, of epistaxis, or any other habitual evacuation in a young man, the habit of high living, &c. This latter circumstance I have often remarked in young villagers coming from the country to Paris, and placed in comfortable houses where they were better fed than at home; six months after arrival, they were in a plethoric state, and were suffering under inflammatory diseases. In this case the san-

guineous system becomes full, the heart is more vigorous and drives the blood forward with impetuosity; a congestion and after it a phlegmasia occurs. Almost all those who have an habitual hypertrophy of the heart are in a permanently predisposed state to congestions of the epigastrium, of the hepato-gastric region, and, on the super-vention of the slightest cause, they are attacked with a gastro-duodenal inflammation which persists, and is renewed for a long time in the acute degree in young subjects, but become chronic in a more advanced age. In place of this hyphertrophic disposition of the heart, it may be some violent effort, a rapid and prolonged walk, rapid running (this is among the *gesta*), that accelerates the circulation and produces congestion; this is more particularly seen among troops, after quick marches, on their arrival at their destination; each one continues to go about his duties; and, these performed, they go to rest; then it is that a congestion forms and passes to the inflammatory condition, and more certainly if cold seconds the other causes. Here the cause is less simple than in the preceding cases, or rather there are several acting simultaneously, to wit, acceleration of the blood's progress, muscular fatigue, cold, and the consequent congestion and irritation.

Let us dwell a moment on the predispositions that favour the congestive causes. Observation proves, that sanguine and irritable persons, with voracious appetites, who eat and digest great masses of food, are the most exposed to acute phlegmasie of the digestive canal arising from these causes. This predisposition augments, if they have been a long time in action, without producing their decidedly morbid effects, or if, after undergoing several attacks of sickness, a perfect cure has not been effected; in the latter case a chronic inflammatory condition may ensue.

Let us also take account of the influence of heat. I confess that at one time it appeared to me more powerful than cold; but on paying renewed attention, and multiplying my observations on collections of men transported to various latitudes, I became convinced that the majority of gastro-enteritis is caused by cold. Heat, when moderate, prevents them to a certain point by facilitating the passage of the blood to the exterior, and towards the secretory apparatus, which purify it by dispossessing it of its superfluous and useless parts. But when this heat is considerable, and causes great exhalation from the skin, it causes increase of thirst, which thirst is the first sensible effect of heat, and announces that the digestive canal is in a heated state, and its mucus becoming scarce; the fluids you then take are absorbed more rapidly than usual. If this ardor continues, the inflammatory condition may supervene; it is easy, however, for men

that pass from cold into warm climates, to obviate the inflammatory explosion if those climates are salubrious; but if damp fogs and cold winds prevail, and if to these miasmatic exhalations are added, the case is vastly different. In warm latitudes a considerable evaporation takes place during the day, principally on the sea shores and banks of the rivers; and the vapour, in precipitating during the night, produces atmospheric cold. Add to this that the days and nights are there of almost equal length; without these two conditions they would scarcely be habitable: were the days in the torrid zone as long as those in the frigid zone, no man could exist in it. The exaggerated action of the skin acts sympathetically on the digestive canal, and the more it augments, the more the latter becomes irritable. This canal is therefore placed in a state of inflammatory predisposition, upon which cold and dampness ensue, and give rise to internal congestions and inflammations of excessive violence; so that here too we may say that cold has very much to do with their development, and it is more reasonable to suppose so, as man mostly prefers a residence on the shores of the sea, or the banks of large rivers, where it is cooler than in the interior. This is a distinction that I now make for the first time, and which to my knowledge has been no where else made; and it is confirmed by the manner in which Europeans most readily acclimate themselves in equatorial countries; they are told to go during the summer, and live in the vallies and plains, away from the banks of the rivers.

Remains to mention the part which the fluids may enact in the etiology of gastro-intestinal inflammations. Plethora in itself, consisting as it does in a predominance of fibrine and cruor, only constitutes a predisposition; a determining agent is requisite to make inflammation supervene. If people are fed on animal food combined with aromatic and stimulating substances, they give the sanguineous predisposition an increased activity. The urine and other depurative fluids become more irritating, but this scarcely constitutes anything but a more powerful predisposition, and almost invariably directly irritating causes are required to cause the outbreak of the inflammation. The influence of other inflamed tissues is also to be appreciated in gastro-enteric phlegmasiæ; we have spoken of such in treating of external inflammations, and we shall return to it hereafter.

These inflammations of the digestive canal are a most important subject, for having been hitherto unknown, they are now the object of examination and discussion to all medical men. These discussions will continue until the general opinion has had time to become fixed. Men who proceed attentively in the study of one object, become acquainted with it long before others, and are bound to grant

those who give less attention to it, or are endowed with less powerful faculties, the means and time for acquiring it. In this plight is the question of inflammations of the digestive canal at the present time: I say not this with asperity or with a sneer: I have nothing in view but the good of science, and if you sometimes see me testify impatience, it is only at the obstacles that are placed in its way. I have the happiness, or if you choose it, the misfortune to be an enthusiast of truth—that is all.

The inflammations of the digestive canal may be considered in the three principal regions of that canal; in the upper or gastroduodenal, in the central or small intestine, and the lower or great intestine, comprehending the cæcum, colon, and rectum. All these may be complicated, but there are cases in which they are more or less isolated.

As regards the mucous membrane itself, it ought to be considered in a much more extensive light than has been hitherto done, even by Bichât—a name I venerate for the stupendous strides he caused medicine to make during his brief career, and for the great share he had—and that I proudly attribute to him—as my master and chief guide in establishing the physiological doctrine, the basis of which he furnished. However, the mucous membrane of the digestive canal ought not to be considered simply as an organ of nutritive absorption and elaboration, but as an internal sense possessing the greatest influence, rich in nerves and nervous papillæ, and capable of transmitting stimulation throughout the economy, and chiefly to the nervous centres, whence it is everywhere reflected; and this it is that renders the inflammation of this part different from all others. 'If you read the *Traité Anatomique de l'Inflammation* of M. Gendrin, you will see how much he insists on the presence of these papillæ; I do not mention the physiological inductions he makes from them: I merely wish to draw your attention to this pervous exuberance of the gastro-intestinal mucous membrane, and to point out to you beforehand the reason of the peculiar physiognomy of these inflammations, which is also that of their numerous forms, of their multiform causes, and of the slowness with which they have been recognised. In enumerating these causes, I did not sufficiently insist on a set of modifiers to which I must now return. I allude to drinks, which are not only used for the purpose of satisfying our thirst, but as luxuries.

If you would form a just idea of the action of these fluids, you should divide them. The least active are cider and beer, and other analogous beverages made from vegetable substances in a state of forced fermentation. These are hurtful on account of the acid and bitter principle they contain, and which in some degree correct their effect by their diuretic property; still they are intoxicating, and if too freely taken may stimulate the

stomach in a noxious degree; cider especially, from the mucilage it holds, may produce dyspepsia. Next comes wine, which is divisible into numerous sections. Wines that contain more acid than alcohol are less exciting than those which include those principles in the inverse proportion. But acid itself is an excitant, since all concentrated acids are corrosive; the superexcitement produced by acids depends on the state of the gastric passage, and cannot sometimes be tolerated even when diluted with water. Southerly wines which contain great proportions of extractive principles, of colouring matter and alcohol, more readily cause gastritis than the preceding ones. Sweet wines have this property in still higher degree. Those which have the least of it, and which stimulate the stomach the most favourably, are old wines that time has deprived of their alcohol and colouring principle—Bordeaux wines, for instance: persons who desire moderate gastronomic joys prefer these, while those who require excitement seek the strong kinds of wine: taken in moderation they rarely induce gastritis. Sweet wines, as those of Malaga, Jurançon and the Pyrenees, are treacherous by their mild taste and by the alcohol they are charged withal: while drinking them, you would imagine you were swallowing milk; but they are fiery and light up a permanent ardor or exaltation of the visceral nervous system.

There are some beverages which in their preparatory stimulation to gastric inflammations act roughly and cause such a degree of irritation as to produce catarrhal affections: of this kind are bad cider and wine. Such is the case also with acid vegetables and putrid aliments which are digested and elaborated with difficulty. Agents of this kind produce a mischievous stimulation on the digestive canal, that gives rise to acidities, diarrhoea, mucous flux, in short to catarrhal irritations, and to that form of gastro-enteritis which has latterly been attempted to be transformed into a particular disease denominated *dolhinentery*. On the other hand, fine and choice wines exalt more particularly the nervous tissue of the mucous membrane, or its nervous papillæ, and induce more purely inflammatory gastritis.

Among medicinal agents also there are some distinctions to be made. Bitters for instance, almost always act in a similar manner to choice wines; whereas tonics, such as saline and mineral substances, occasion a mischievous shade of gastro-enteritis that makes inroads on the very structure of the tissues. Every medicine has its own mode of action as well as its day of fashion, during which people are occupied in ascertaining its effects, and beholding the fall of its *prestige*. Such is the case with calomel, and the abuses of it in these days may be readily verified. I will venture to assert that both it and all mineral substances indiscriminately employed produce a gastro-enteritis, that puts in

jeopardy the irritability of the mucous membrane: those who have abused it, have their digestive power ruined, and never properly recover health.

MANUAL OF OPERATIVE MEDICINE,

BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

By GREVILLE JONES, Esq.,

Lecturer on Anatomy and Physiology.

Of Bleeding in the external Jugular Vein.—

The patient being seated and his breast and shoulder covered with a cloth several times doubled, a thick compress is to be placed on the vein close to the clavicle; a handkerchief is to be rolled up and placed upon this, its two ends being carried into the opposite axilla, where an assistant holds and draws them tight. The vein now swells, and the operator, placing his thumb on the compress and his forefinger an inch higher on the jugular vein, in order to stretch the skin and fix the vessels, passes his lancet pretty deeply, and makes an orifice larger than when operating on the arm. If the blood does not flow, the patient should make movements of mastication. If it runs down the neck, it may be directed into the basin by a card folded into the form of a trough. The bleeding ended, the compress is to be removed and the wound closed with plaister. If that be not sufficient, a compress may be added held by a circular bandage tied round the neck with a moderate degree of tightness.

Several other vessels have been recommended. The ancients bled on the hands and fingers; some authors have proposed the frontal, angular, lingual &c.—Lisfranc even the cephalic, where it is found between the deltoid and pectoralis major. But where bleeding from the veins we have mentioned is insufficient—and the same is the case with regard to leeching and cupping—our best resource is arteriotomy.

5. *Of Arteriotomy.*—The only artery that is opened is the anterior branch of the temporal artery, which is easy to follow under the skin of the forehead, either by the sight or by feeling its pulsations with the finger. The patient seated or lying, the point where the incision is to be made may be marked with the nail. The skin is to be stretched with the left thumb and forefinger. With the bistoury held in the third position a short incision is to be made, rather by pressing than sawing, so as to divide the artery partially. The artery may be compressed by three or four pyramidal compresses secured by a circular bandage, which may be left on eight or ten days, or till the artery has become obliterated.

SECT. II. REVULSIVES AND EXUTORIA.

1. *Of Sinapisms.*—With mustard-meal and

cold water cataplasm is formed, which is to be applied bare on the skin. In about three hours the skin becomes red, tumid, warm, and painful; at this time the cataplasm should be removed. It has been advised that we should add salt, oil, &c., but these additions are useless, and the ancients well understood that vinegar, so generally recommended, is an addition that enfeebles the action of the mustard. The liquor of Pradien is a kind of sinapism. It is spread over a linseed-meal poultice, applied bare to the foot or leg. The skin does not become red, but an intolerable pain is produced in the heel. In many cases of gout it is attended with wonderful effects.—(Halle).

2. *Of Vesicatories.*—A multitude of vesicating substances have been employed. In the present day they are confined to boiling water and cantharides. In using boiling water there are two methods of proceeding—that of *Mayor*, and that of *Carlisle*. In that of the former, a metallic hammer with a flattened head is plunged into boiling water and applied naked to the skin. Carlisle's method is to apply a fold of wet linen on the skin, and to move over that a nummular cautery heated to a dull red colour.

In applying cantharides, *the usual method* is to spread on linen or skin an epispastic plaister, surrounded by a border of diachylon about three lines in breadth. The plaister is to be covered with a layer of powdered cantharides either dry or moistened with vinegar. The skin is to be shaved and moistened before the plaister is applied, which is to be kept in its place by a bandage or other means. After twelve, eighteen, or twenty-four hours the plaister is to be raised. If we wish to produce only what is called a *flying blister*, the epidermis is to be punctured, merely the serosity allowed to escape, and the surface dressed with fine lint; if we wish to produce a *suppurating blister*, the epidermis is to be entirely removed, either by tearing it away or by cutting it all round with scissors. In Bosquillon's method, the blistering plaister is removed at the end of six hours, and if the skin be red, a linseed-meal poultice is applied, which sufficiently raises the epidermis. The object of his method is to diminish the time during which the cantharides are in contact with the skin, and thus to obviate their absorption and their effects on the urinary organs.

3. *Of Issues.*—An issue is a small round ulcer which is kept open by the insertion of a pea. It may be practised on any part of the body, except in the immediate neighbourhood of a bone, tendon, large vessel, nerves, or the middle of a muscle. The cellular interstices where the skin is far separated from the deeper seated parts, is usually selected, for example, in the *arm*, the fossa which separates the inferior angle of the deltoid from the biceps, and which may be rendered very apparent by bending the fore-arm and contracting the biceps—in

the thigh, the fossa situated on its inner and lower part above the knee and between the vastus, internus,² and tendon of the third abductor—in *the leg*, the fossa below and on the inner side of the knee which separates the inner head of the gastrocnemii from the united tendons of the sartorius, gracilis, and semi-tendinosus. An issue may be made with a bistoury, by incising a fold of skin so as to make a wound from four to six lines in length. It may be kept open for some days with a firm little ball of charpie, and then a pea inserted; the pea may be used from the first. The issue may also be made by the application of caustic potass, the mode of employing which we have before detailed. Or an issue may be made by fixing a pea firmly with plaister on a surface which has previously been thoroughly blistered. The pea will eat its way into the flesh, but it is a long and painful process.

4. *The Seton.*—This is formed by raising a fold of skin, penetrating it with a straight bistoury, or with Boyer's needle, and introducing a thread, or a band of linen unravelled at the edges, or a skein of silk. A portion of the silk is drawn through at each subsequent dressing, until the whole length is exhausted, and then a fresh skein may be introduced with an eye-probe.

5. *Of Moxa.*—A slight scar is produced on the skin by the combustion of an inflammable substance. A multitude of substances have been recommended; the tow used by artillery-men, flax, hemp, the pith of the sun-flower (Percy), the down of the leaves of mug-wort (Sarlandiere), phosphorus, camphor, essential oils, gun-powder, &c. Carded cotton is generally employed. In the *ordinary mode* of proceeding, the carded cotton is wrapped in a band of linen, which is sewn around it moderately tight, so as to form a cylinder, the diameter of which is from eight or twelve to twenty lines. This cylinder should be divided with a razor into portions of from eight to ten lines high. The moxa thus prepared, and held between a pair of forceps, in a piece of card perforated by a hole (Boyer), or by a particular *porte-moxa* (Larrey), is to be lighted at one end with a candle, and its other extremity applied to the skin, which should be previously moistened with saliva. The fire is to be kept up by gently blowing it; but at the Hôtel-Dieu they steep the cotton in a strong solution of nitrate of potash, which renders blowing unnecessary*. *Regnault* interposes between the skin and the moxa a thick piece of wet cloth. This method is recommended in hydrocephalus.

SECT. III. VACCINATION.—It comprises the means of collecting the vaccine matter, and the method of inoculating it. The

* A solution of acetate of lead is equally good.—T.

matter may be collected in a tube of glass, or the quill of a pen, hermetically sealed with sealing wax, and thus the matter may be preserved many months. Ordinarily it is collected between *two plates of glass*, the edges of which should be united by wax or isinglass, and they should be wrapped in sheet-lead, to preserve the matter from air and light. When collected on lancets, the matter of one vesicle is enough to charge several of these instruments, but it will not keep long. The most favourable time for collecting the vaccine matter is from the sixth to the seventh day; at a later period it loses part of its strength.

As to the *inoculation* of the vaccine matter, a multitude of proceedings have been described. We choose, as the simplest and surest, that employed at the Royal Academy of Medicine. The point of a lancet is charged with vaccine matter. If the vaccination be performed direct from one patient to the other, it will be proper after each puncture to recharge the lancet from the opened vesicle. If dry vaccine matter be made use of, it will be necessary to moisten it with a drop of water or saliva. Three punctures are usually made in each arm, about a finger's breadth from one another. They are disposed in a vertical line, or so as to form a triangle, but the matter is of little importance.

The point of the lancet being presented horizontally to the skin, is plunged under the epidermis about half a line in depth. Commonly a little blood flows, which is of no consequence. After we have left the instrument in the above position three or four seconds, it is to be turned in the wound, so as to open this and facilitate the introduction of the matter; and the flat surfaces of the lancet should be wiped against the borders of the wound. Each puncture will occupy seven or eight seconds. The wound is left to dry in the air, and care must be taken that the clothes do not rub it.

SECT. IV. ACUPUNCTURE.—The acupuncturating needle is usually made moderately slender, about two inches or more in length, terminates at one end by a point, and is surmounted at the other by a small steel handle. A small ring is added to the lower part of this handle, when the needle is intended for electro-puncture. There are two modes of making the puncture. In the first, the needle is applied perpendicularly to the skin, and the handle rolled between the thumb and finger, and gently pressed until it penetrates as far as may be requisite. The middle of the needle may be supported by the left hand, and on drawing it out the same rotatory movement should be made. In the second method the needle is struck on its handle by short rapid blows of a small mallet. It is quicker and less painful than the rotating plan.

Electro-puncture.—The needles being implanted by one of the preceding methods, a Leyden jar is discharged upon them by re-

peated shocks, or as they are put in communication by means of wires with the two poles of a galvanic battery.

M. Coster applies electricity without needles. Having rubbed one side of a bronchocele with a quarter of a grain of pure iodine, and having passed a galvanic current through the tumour, by placing its extremities in connexion with the poles of a voltaic pile, his treatment proved completely successful. He considers that by this method he facilitated the absorption of the iodine.

(To be continued.)

Reviews.

Digest of the Evidence given before a Committee of the House of Commons.—Extent of Intemperance in the United Kingdom. By John Edgar, Professor of Divinity in the Royal College of Belfast. 12mo. pp. 192. London: Bagster.

WE resume our notice of this work on account of the importance of the following evidence, which is the most correct we have seen on the subject. We, however, are firmly convinced that a moderate use of diluted ardent spirit is as wholesome and as essential to health, as that of wine or other fermented liquor. The Temperance Societies appear to us to have split on Charybdis in avoiding Scylla. They should not have attempted to proscribe spirituous liquors and pass over fermented. We entirely agree with them on the demoralizing effects of intemperance, but we totally deny that spirituous liquors are entirely the cause. The medical profession are of our opinion, as appears from the insignificant number which has joined the societies. We would suggest that the abuse of all liquors should be denounced in future, and when this is done, our brethren will universally promote the laudable objects of Temperance Societies.

“*Dr. Robert Greig Dods.*—2589. Have you had much opportunity of observing the habits of the lower orders?—I have.

“2590. Is there anything peculiar in the circumstances of those most addicted to intemperance?—There are three circumstances which seem to influence their habits; the first applies to those who have some small means of subsistence, independent of their own efforts to procure their support; the other refers to those who are perhaps superior to the majority of others in the same circumstances and condition of life, and are not unfrequently found acting prominent parts in convivial scenes; the third comprehends those who are regularly dull and sensual.

"2591. When want of employment has prevailed, have you noticed any improvement in their conduct?—I have observed less excess in the use of ardent spirits.

"2592. Do high or low wages tend more or less to habits of drunkenness?—I have noticed that habits of drunkenness are frequently very much increased by high wages; and I remember a circumstance which tends to place this fact in a striking point of light. During the time that pretty good wages were paid to the operative mechanics in the different districts in Scotland, habits of drunkenness prevailed very extensively. When depression arose, and they had less facility in obtaining support, of course tippling might prevail to a considerable extent, but fewer excesses generally were visible. When the depression was removed, and they felt themselves in comfortable circumstances, it was remarkable how quickly they returned to their previous habits of intemperance.

"2593. You think habits of intemperance are as prevalent among the middle classes as the lower classes?—I should think the use of ardent spirits as general, and excessive indulgence in them nearly as common.

"2595. And in the higher too?—The higher classes do not appear so intemperate in their use of ardent spirits, but the majority are by no means sufficiently moderate in wine and other pretty powerful stimuli.

"2596. What neighbourhood are you speaking of?—I am speaking generally of England and Scotland.

"2597. Have you known many persons moving in a respectable sphere in society whose character and success have been injured by such habits?—I have known very many. I have been given to understand that the last detachment of troops sent out to India included upwards of 60 young men who had been moving in respectable circumstances, and who had been brought to that condition chiefly by their intemperance.

"2598. Had been induced to enlist?—Yes.

"2599. Is it not true that the East India Company's army is frequently resorted to by such parties, who desire to go abroad to avoid the shame and degradation of being seen in the army at home?—It contains a great number of such individuals, very few of whom ever return to repair the disgrace and misery they have brought upon themselves.

"2600. Are excesses similar to those you have described at all common among those who are qualifying themselves for the learned professions as students?—I regret very much to say that they are too common.

"2601. In what branch of the learned professions; medicine?—They apply chiefly to medicine and law; perhaps more to medicine. In order to prevent the excesses to which such men go, and with the view of checking intemperance among other classes

of the community, an association of medical men, consisting of physicians, surgeons, and students, was formed at Edinburgh in February, 1832, with the 'Resolution to abstain from the use of ardent spirits, except for medicinal purposes, and to refrain from giving them to, or countenancing the use of them by, persons in their employment; and that as the promotion of temperance in general is an object of the institution, other liquors though allowed, if used to excess, must necessarily exclude from membership.' This association ranks among its members some of the highest names both in medicine and surgery, and has been the means of reclaiming several talented and promising individuals.

"2602. Do they take spirits as stimulants during severe study?—They rather take them as a relief from study; those who use them freely are generally negligent of study, or soon become so.

"2603. In the first instance, it is intended as a relief after study?—It may with some for a time or two at first, but if frequently resorted to, it unfits the mind for patient investigation, and becomes an agreeable diversion or rather substitute for intellectual effort.

"2604. Are the students of all the different professions equally characterized by such indulgences?—I should think there are very few among the students of theology; the cases are chiefly confined to students of law and medicine.

"2605. At the universities?—Yes, at the universities and colleges.

"2606. Does this habit materially affect their professional progress?—Exceedingly; so much so, that one of the most eminent surgeons of the present day stated in his class-room, in my hearing, that up to the holidays at Christmas, he had noticed the regular attendance of many promising young men; but after the holidays, he was grieved to find many who came very irregularly, and he ascribed their absence chiefly to the habits of intemperance into which they had been led during the Christmas recess.

"2607. Does it at all influence their intellectual or moral character?—It influences that still more perhaps than even their professional progress. I have known young men of exceedingly promising intellectual habits, and of reputedly high moral character, who by a few follies of that kind have become injured in both respects. I have seen young men, by habits of intemperance, not only prevented from making all further progress in professional knowledge, but so degraded before the world, that they have been banished from their homes, and either subjected at once to menial employments, or sent to some foreign station as a relief from the shame and ignominy which they had brought on themselves and their friends.

"2608. Do the same indulgences at all

exist among medical practitioners?—I regret to say they do to a considerable extent.

"2609. What are the general qualities of such men?—You find medical practitioners of that class generally of an agreeable and social character; they are what are called pleasant fellows, agreeable men.

"2610. Jolly companions?—Jolly companions; who, possessing a strong relish for society, and taking a prominent place in its entertainments, become addicted to habits which cause them to neglect their profession, and disqualify them for discharging its duties properly.

"2611. Have you known any flagrant evils inflicted on patients by such propensities on the part of the medical gentlemen who attended them?—I remember several most painful cases; in one instance, a patient who required surgical assistance received irreparable injury.

"2612. Describe the nature of it?—It was a midwifery case, in which the application of instruments was necessary, and the practitioner, from the state of intoxication in which he was at the time, applied them injudiciously and rashly, and left the patient during the rest of her life in a most miserable and hopeless condition.

"2613. Did the woman die?—She did not die, but dragged out a miserable existence. I remember several instances in which most valuable lives were sacrificed to the drunken habits of the medical attendant, who instead of treating inflammatory attacks and other severe maladies with promptness and decision, encouraged the patient to use ardent spirits as the best remedy which could be applied, for the base purpose of obtaining his share in the beverage. Such treatment of course not only aggravated the symptoms, but delayed the only remedies which could prove successful, and the patient sunk under an attack which, humanly speaking, but for the intemperance of his physician, might have been easily and speedily cured.

"2614. Are you aware at all of persons more correct in their conduct generally and more moral, clergymen and others, yielding to those habits?—Yes; I have the pain to know several clergymen who are addicted to habits of intemperance. I remember one who became a common soldier from such indulgences.

"2615. Was he expelled his profession?—Of course.

"2616. For gross and open immorality?—For gross and open intemperance. I know others who at present are filling menial offices, from the same indulgences; and I know several who have been expelled from their churches, and are living in disgrace with their relations or others, on whom they depend. In churches where the same strict discipline is not exercised over all the ministers, frequent excesses are by no means uncommon; the parties, however, are not interfered with, but are allowed to hold their

offices, to the annoyance and injury of the community.

"2617. Have you observed habits of intemperance in females?—I have; there is a pretty general tendency to the use of ardent spirits in certain circumstances among females, especially during the time of nursing; and there is a practice rather too common among females even in respectable life: I refer to morning calls, and the like, at which stimulants or cordials are taken, which are always more injurious than beneficial, and in time beget a love for ardent spirits.

"2618. Which custom you think leads very much to an increased desire?—Yes, and to a confirmed habit. This is so well known to medical men that a very eminent professor is in the habit of frequently cautioning his students against mistaking symptoms arising from the use of cordials, and the like, for those produced by actual disease.

"2619. Have you seen any bad effects arising to children from the use of ardent spirits?—Yes, some of the most lamentable effects. The principal cases in which they are administered are to soothe infants or little children, in the shape of small portions of gin-toddy and other stimuli; some parents practise the baneful habit of giving their children, even in health, small portions of their own stimulant beverages.

"2620. What effect is produced upon the constitution of the child by that habit?—The first effect produced is a sort of pleasant excitement.

"2621. What injurious effect has it on the constitution?—It leads ultimately to glandular diseases, especially of the bowels, to subsequent emaciation, and almost certain death.

"2622. Does it not prevent the growth and full development of the muscular powers of the child?—Exceedingly.

"2623. So that the habit of drinking, especially when begun early, leads to deteriorate the race?—Very much; alters their muscular and energetic character; and if the practice be continued, the child sinks under it at an early age.

"2624. Speaking as a medical man, should you say the progeny of intemperate parents were less healthy in all their functions than the offspring of temperate parents?—They are.

"2625. Is there any difference in the appearance of such children at their birth?—Sometimes not appreciable, at others quite distinct; the infant has frequently not merely a want of healthy aspect, of plump, round outline, but a starved shrivelled, and imperfect look.

"2626. Then as far as the effects of intemperance on the human constitution are deleterious, those effects are accumulative, being more and more deleterious in proportion as the offspring extend?—Certainly.

"2627. That is to say, supposing there

be drunken parents in the first instance, and the children of the drunken parents have become drunkards too, the offspring of the third and fourth generation would go on deteriorating too?—They would; and the worst of it is this, that the child of drunken parents inherits an hereditary predisposition to the use of ardent spirits; for parents suffering under disease of the liver, or any other organ, from the excessive use of spirits, gave rise to children whose constitutions possess strong tendencies to similar morbid actions, and these morbid actions not only lead to habits of intemperance, with the vain hope of relief from uneasy sensations, but are greatly increased by such practices. In fact improper indulgences of any kind, when persisted in by the parents, and repeated by their offspring, tend to debilitate succeeding generations, and render them liable to the most painful and incurable diseases; hence scrofula, and a host of other maladies.

"2628. So that you conceive the possibility of the race becoming extinct by excessive inebriety?—Yes, by such habits one generation after another becomes more and more effeminate, till they scarcely deserve the name of human beings.

"2629. Then, in a national point of view, considering the strength of the country to consist mainly in a vigorous and healthy population, you conceive intemperance to be a great national evil, and one greatly leading to the deterioration of the race?—Yes, a great national evil, constantly tending to produce those effects.

"2630. So that, in a national point of view, do you conceive it to be the duty of Government to interpose as far as it can do to prevent the further progress of this evil?—It is their imperative duty, if they wish to preserve a vigorous and athletic population.

"2631. Have you observed much the habits of soldiers and sailors?—I have to a considerable extent observed their habits, and find them of a very lamentable, intemperate character.

"2632. What causes seem to you to have contributed to form their habits of intemperance?—There are several causes; first, a fixed provision for their necessary wants, with the power of saving small sums, which at intervals they spend in drink; another grand cause is the example of their superiors.

"2633. Any other?—Perhaps the strong predisposing cause is the want of social and domestic comforts; together with the total absence of anything like suitable arrangements on the part of Government for the extensive and permanent improvement of their intellectual and moral qualities.

"2634. Does not the issue of spirits by the Government in rations to soldiers and sailors give countenance to the opinion that ardent spirits are necessary for their habits, and may not this also contribute to form the

habit of constant drinking?—It does in a very striking degree.

"2635. Do you think the issue of such rations beneficial or injurious?—Extremely injurious.

"2636. You can conceive no case in which they are necessary?—None, in which they ought to be regularly issued.

"2637. You can conceive many cases in which they are deleterious?—Almost every case.

"2638. At which of the universities has your experience chiefly laid?—At the university of Edinburgh.

"2639. The habit of drinking, I suppose, is first formed by the inducements of society, or from stimulants being supposed to be useful under a delicate state of health?—They are chiefly induced, among the students, by a love of social enjoyment, and by a dislike to study.

"2640. No man, when he intends to drink, intends to become a drunkard?—Certainly not; and no one thinks himself a drunkard though he may indulge to a considerable extent.

"2641. Has the habit of drinking generally a tendency to demoralize the mind?—A very strong tendency.

"2642. Makes it more difficult for the individual to distinguish between right and wrong, not merely in cases of drunkenness, but in other moral points of view?—Yes; and they prevent his being able to occupy his mind with high moral and intellectual questions.

"2643. Then it has a tendency to give him a disregard for truth?—A strong tendency to that effect.

"2644. It requires so strong an effort of reason or of morals for a man to throw off habits of intemperance, that the drunkard is to be pitied?—He must be treated like a child or a madman.

"2645. Then you conceive the Legislature would be acting the part of a parent towards the State by withholding the temptations to drunkenness?—Certainly; the most beneficial effects which could follow to an intemperate individual would be salutary restraints and want of facilities for drinking.

"2646. Speaking as a surgeon, are not wounds more difficult to cure where the parties have been addicted to strong drink?—They frequently resist all means of cure.

"2647. Then, as regards the efficiency of the army in times of war, it is highly important that temperance should prevail among the troops?—In order to enable them to undergo fatigue and make exertions of any considerable amount, they ought to be kept strictly temperate.

"2648. Is it not the fact that a man addicted to drinking may die of a slight wound, while a man of temperate habits will recover from a comparatively severe wound?—It is the fact.

"2649. Do you consider spirits properly

designated as poison?—Under a proper explanation of the term, they may be justly called poison; they are ranked by writers on medical jurisprudence among the narcotico-acrid poisons; their deleterious action depends very much on the constitution of the patient and the amount taken: small quantities seldom produce effects which the patient thinks to be hurtful; but, if repeated, they always prove more or less injurious; larger quantities frequently prove fatal, by directly producing effects analogous to other poisons, or by giving rise to other diseases, which, in a short time, cause death: very large doses often destroy life within a few hours, and are known to act on the same principle with other narcotics.

"2650. Are the usual effects of death by other poisons observable in cases of death from spirit drinking on a *post mortem* examination? That is, is there any difference observable in a death occasioned by spirits from poisons of any other kind?—The morbid appearances seen after death occasioned by ardent spirits exactly agree with those which result from poisoning caused by any other substance ranked in the same class.

"2651. Do you consider it dangerous suddenly to break off from habits of drinking?—Constitutional inconvenience would, to a certain extent, follow; but this could be easily removed by slight medical treatment. I might add, that the inconvenience is so very trifling, that it should not be taken into account by the Legislature; while the evil, if persisted in, is so great, both as it respects individuals and the community, that its cure demands their prompt and imperative interference. The abandonment of intemperate habits gives the chance of future comfort and health; but their continuance almost certainly secures premature disease and death. No one is safe from the approach of countless maladies, who is in the daily habit of using even the smallest portion of ardent spirits; the practice cannot possibly do any good, and it has often done much harm.

"2652. Now what in your opinion are the general causes that have led to the habits of intemperance that prevail?—They seem to me to be of a two-fold character; certain physical tendencies, and certain moral tendencies; the physical tendencies appear to be, first, constitutional predisposition; secondly, certain articles of diet; in the third place, improper sensual indulgences; and lastly, other habits, such as smoking, snuffing, and the use of other artificial stimuli.

"2653. What are the physical conditions of the system that lead to such excess?—Predisposition, which I have already mentioned in my evidence, seems to me one of the causes, which is extremely apt to be overlooked.

"2654. Whence arises this predisposition?—From the intemperate habits of the parents.

"2655. That would leave an hereditary predisposition on the part of the offspring?—Yes; and its mode of action I have before attempted to explain.

"2656. What are the articles of diet that produce a desire for stimuli in drink?—They are articles which are either improper in quality, or in quantity, or in both; those of the last class are well exemplified in the diet of the poor classes, both in Scotland and Ireland, which consists too exclusively of farinaceous food, such as meal and potatoes. Such articles, without a proper portion of animal food, do not afford sufficient nourishment, unless the quantity be considerable. This occasions too much distension of the stomach; indigestion and flatulence occasion a sense of uneasiness. This induces the patient to apply to ardent spirits for relief; the relief is felt to be agreeable, and as the articles of diet are still persisted in, the stimuli are again resorted to, and so on till the habit be confirmed. In England, among both poor and rich, the articles of diet which seem chiefly to lead to the use of spirits, are such as are objectionable, partly on account of their nutritive or rather indigestible qualities; large supplies of indigestible food, such as pork, pastry, puddings, pies, shell-fish, and other improper articles, are taken too freely by the mass of the English population, and are felt burdensome upon the stomach; and in order to relieve this weight by assisting digestion, in other words, to enable the stomach to go through its increased labour, small quantities of ardent spirits are given it by way of bribe. We know it is proverbial that certain kinds of diet, such as fish, certain puddings, and pastry of different sorts, require a dram after them; and the majority of persons who indulge in such articles seldom fail to use a little brandy, or some strong stimulant, as a corrective, according to their view of the subject.

"2657. But spirits do ultimately lead to indigestion, and to the diseases sought to be cured?—Yes; and I should say that government, while legislating for the cure of the evil, should take into account and fairly delineate the predisposing causes, and the inefficiency of other means while these exist. You never will make the English or Scotch population temperate to the extent desired, without giving intelligible information as regards the effect of their diet, and if possible, correcting their false notions respecting the real qualities of ardent spirits.

"2658. How do sensual indulgences lead to intemperance?—They act mutually on each other: intemperance leads to improper indulgences, and these again to intemperance. The demands which they make upon the vital energies seem to leave a sense of oppression, debility, and uneasiness, from which relief is sought by artificial stimuli: these in their turn, prompt to similar excesses, till premature decay destroys its thoughtless victims. Ar-

dent spirits are the *primum mobile* of that infernal machinery, whose complex movements have converted 'whatsoever things are lovely and pure' into every thing most base and polluted.

"2659. How does smoking lead to intemperance?—It begets habits of excitement, and produces a desire for fluid. Some men have the power to resist the use of any thing stronger than water; but the majority resort to powerful stimuli.

"2660. What are the mental conditions which favour intemperance?—They are various; extremes of any kind; such as fear, grief, disappointment, anxiety, want of consideration, want of self-esteem, the influence of fashion, and the like.

"2661. They might think if the population were better instructed as to the evil resulting from the use of spirits, that they would be less disposed to apply to them as a remedy in such extremes of mental oppression, &c.?—Yes; especially since there are remedies which could produce happier effects without injurious results.

"2662. Is there no reasonable probability of that information being speedily so circulated among the people as to put a stop to drunkenness?—There is a strong probability, provided those who are qualified to judge and give an opinion on the question were to record their judgment, and have it circulated through the country by means of newspapers or pamphlets.

"2663. The Temperance Society might spread that information with great rapidity through the country?—To a great extent; and I think they would do more for the cause by avoiding unceasing discussion on the moral question; for, however important, and however deeply felt it may be by even the mass of the people, yet unless men feel that their bodies are really injured, they will not be persuaded by the soundest arguments.

"2664. But as minds are differently constituted, the moral part of the question may be more immediately essential to some than the medical consideration?—These might be properly combined; and if the real physiological effects were fairly and intelligibly stated, and were enforced by moral considerations of the highest character, the public in general could not resist the evidence. When the Temperance Society says a great deal about the moral bearing of the subject, and the enormous evils resulting to the community from the excessive use of ardent stimuli, the public in general vaguely confess the truth of all they say, but they do not feel the force of moral obligation to be so great as decidedly to influence their conduct, especially when from habit they have been brought under the power of ardent spirits; but if you can bring the subject closely 'home to their own business and bosoms,' if if you can make it tell upon their persons, and show them that those habits destroy their physical enjoyment, and certainly lead

to the production of disease sooner or later, they would be more alarmed at the consequences, and more disposed to abandon their habits.

"2665. Are there no conditions of the system in which ardent spirits prove beneficial? are they not useful for long-continued mental or bodily efforts?—There are a few cases in which they may be administered with benefit under medical superintendence.

"2666. Do they not tend to lessen the exhaustion which such exertions produce? They are extremely injurious when given to restore vigour after fatigue, or to protect against extreme cold; for, in the first instance, they heighten the excitement, which was the evil complained of, and in the next, the relief is exceedingly temporary and transient, and leads to debility and languor, which afterwards greatly increase the evil, and soon leave the patient under greater languor and chilliness than before.

"2667. Has it come within your knowledge that the guards and coachmen of public conveyances have discovered that the water-drinker sustains the effect of cold better than the dram-drinker?—I have observed that circumstance, and it is now generally admitted as a fact.

"2668. So that here is an instance where an accurate knowledge of the effect produced has led to a reform in the habit?—Certainly.

"2669. And the extension of a similar knowledge in the other classes of society would be likely from motives of self-interest to produce the same effect?—Undoubtedly.

"2670. What moral influence could be brought to bear on the habit of intemperance generally?—The grand moral influence appears to me such as the Temperance Society attempt to exercise on the question; first, the example of the respectable and intelligent among the community, and next, a fair statement, without prejudice and without any exaggeration, a fair and candid statement of the legitimate effect of spirits on the human constitution.

"2671. What are some of the principal evils produced by intemperance on the constitution?—First, a dangerous general excitement; secondly, subsequent debility; those are the general effects produced.

"2672. What are some of the partial evils?—Diseases of the brain, of the liver, of the heart and blood-vessels, of the kidneys, of the stomach, of the pancreas, of the bladder, of the skin, &c.

"2673. Are there any other maladies, connected with the derangement of one or more organs, arising from intemperance?—Apoplexy is a very common result from intemperance, insanity is not unfrequent, mental delusions are often seen, delirium tremens, and a most fearful disease, which though not very common, has been repeatedly witnessed, spontaneous combustion.

"2674. Have you ever yourself known an

instance of spontaneous combustion?—I have not.

"2675. Do you know anybody on whose testimony you can rely for the information?—I know only those who have written on the subject, Grotzner, Beck, and others.

"2676. Are they physicians?—Yes; and I recollect a case given in the newspapers a few years ago of a lady in London.

2677. But from your knowledge, as a medical gentleman, do you conceive spontaneous combustion possible?—Quite possible.

"2678. It would not be prevented by the existence of the moisture there is in the body?—The moisture would rather tend to favour the combination of elements which are concerned in producing this horrible effect of intemperance. What condition of the system tends to such a fatal issue, or how the various fluids and solids of the human body acquire a chemical constitution fitted for such a phenomenon, it is difficult to explain; but it is well known that alcohol contains in itself all the elements of olefiant gas, with oxygen and hydrogen in excess, and by persisting in the habitual use of alcohol, it is not improbable that after a while its elements might assume that combination which would give rise to such a catastrophe.

"2679. Do habits of intemperance at all interfere with medical treatment in cases of disease?—That forms one of the strongest points of evidence on which a medicalman can give his opinion; there is not a single acute attack which persons are liable to, who are accustomed to the use of ardent spirits, which we have much hope of being able to cure; the probability, as compared with similar attacks on temperate persons, is as ten to one against recovery. The explanation is simply this: the acute attack coming on, requires the abandonment of intemperate habits, prompt treatment, free blood-letting, and other active remedies, which, without his usual stimuli, the patient cannot bear.

"2680. Are there any other habits that influence the patient's recovery?—Another very prevailing habit, which interferes with medical treatment, in a similar degree, is smoking. I have not seen one patient under any severe attack, or who had undergone any painful operation, who made the progress that might have been expected when this habit was suddenly abandoned; and I have always found it necessary to order a renewal of the practice for a time, in order that the patient might get more comfortably through the attack; but if the attack in either case should be so severe as to prevent the patient from continuing his habit of smoking or drinking, his chances of sinking against recovery are as a thousand to one.

"2681. You have mentioned several varieties of mental suffering, arising from intemperance; are any such cases more prevalent at the present day than formerly?—Mental dejection, morbid irritability, ungovernable passion, frightful delusions, confirmed

insanity, &c., seem more common, and are well known as leading not only to some of the worst diseases, such as aneurism, apoplexy, &c., but to the perpetration of the foulest crimes, as duelling, murder, suicide, &c.

"2682. In what class of society?—Chiefly among those who use ardent spirits.

"2683. Whether poor or rich?—Yes.

"2684. Was apoplexy a common disease among poor families?—It was much less common than now; diseases of the heart and blood-vessels was also of comparatively rare occurrence, but is now extremely common. I grant that a number of cases were overlooked formerly, on account of the imperfect method of investigating such maladies, and that now much ought to be ascribed to mental influence, on account of reverses of fortune, more common than formerly among the community; still the experience of medical men fully proves that the use of stimulants forms one of the principal agents in producing these untractable diseases.

"2685. And indigestion, which was formerly considered to be the disease of the rich, has that been on the increase among the poor?—Yes, very much; and diarrhœa during the last five or ten years has been both more common and more severe.

"2686. Among the poor?—Chiefly among them; but I would not be understood as saying that such attacks arose entirely from the use of spirits; a variety of other agents are concerned in their development; but the habitual use of stimulants more than anything else favours the occurrence of such derangement in the system.

"2687. What scheme should you recommend the Legislature to adopt for the cure of intemperance?—I do not feel myself prepared to give any thing like a satisfactory answer to such a question, not being fully aware to what extent Government can go on such a subject; but it occurs to me that all those whom the State has power to control should be placed under salutary restraints; for instance, certain prohibitions might be issued in regard to soldiers and sailors; and when paupers apply for parish relief, it should be ascertained whether they have been addicted to habits of intemperance, and if so, the lowest possible allowance should be given them. It might be wise also to prevent spirits being consumed on the premises, except in certain cases, as by travellers and the like.

"2688. Can you give any physiological explanation of the effects produced by intemperance on the constitution?—The facts that have been pretty well ascertained are chiefly the following: namely, that alcohol coagulates the albuminous and gelatinous parts of the structure, and corrugates the solid parts, as the muscles, &c. Its effect on the blood-vessels seems to be two-fold, increased excitement, and contraction of the diameter of the vessels; this tends to produce enlargement in some parts of the blood-vessels, or effusion,

should their coats give way at any part of their course; diseased deposits are frequently formed where a branch is given off, or in some of the wider portions of the blood-vessels, which give rise to most painful symptoms, such as are common in gout and rheumatism. Increased excitement also, from an inordinate use of stimuli, maintained for a given time, diminishes in proportion to the healthy functions of the organs, and leads slowly, though certainly, to alterations both in structure and function; in this way we may account for diseased liver, diseased kidneys, diseased heart, and symptoms which indicate these in the effusion of serum, which occurs in different regions of the body, and is called dropsy, water in the chest, and general anasarca. Very striking effects are produced also upon the nervous system, as is manifested in the imperfect muscular contractions visible in a state of intoxication, in tremors, palsies, and other maladies which not unfrequently afflict the victim of intemperance. Emaciation and debility, which are very common characteristics of those given to habits of spirit-drinking, proceed from the constitution being robbed of its proper supply of nourishment, while at the same time it is compelled to carry on increased action; this throws it too much upon its own resources, and increases the process of absorption above that of nutrition; so that the body soon assumes a shrivelled and aged appearance; besides, the glands through which the absorbent vessels pass, being kept under constant irritation, become enlarged, hardened, and variously altered in structure, till at last they cease to carry on the functions to which they are destined, and the fluids which they used to transmit become effused into the surrounding parts. The diseased deposits which occur at the heart and along the blood-vessels, seem to be produced by the efforts of the minute vessels which supply these organs to resist the injury that might result to the larger blood-vessels from their increased action, produced by the presence of ardent stimuli; in other words, a given amount of blood, with a given force, and in a given time, circulates through a set of tubes contractile and expandible up to a certain point; these tubes are of a certain length and diameter, and in their healthy condition are capable of affording passage to the blood, according to the usual rate and quantity; but when their diameter is diminished through the influence of spirits, and when the frequency and force of the circulation is, from the same cause, considerably increased, the vessels become strained in some part of their course, and the vital energies, which instantly attempt to prevent or repair the injury, throw out fluids which become coagulated, and remain as mechanical obstacles to the proper discharge of future functions. Many lamentable specimens of morbid deposits are furnished by habits of intemperance, and many 'wearisome days and restless nights'

become the purchase of such thoughtless indulgences. On the same principle might we explain enlargement of the heart, of the aorta, and other parts of the arteries, apoplexy, coma or lethargy, and the like; always taking into account the influence of vital action, and a combination of other causes aiding or resisting the various results. It were easy to extend my remarks on this part of the subject to a much greater length, but enough has been said to convince those who will yield to facts, of the injurious effects ardent spirits, when used even moderately for any length of time. If the thoughtless consumer, or zealous advocate of strong stimuli, would accompany us to a few *post mortem* examinations of individuals who have persevered in such habits, or were called to witness life in the sufferings they previously endured, they would feel horrified at their own folly and ignorance, and if they were wise, would never touch the dangerous bowl again. But whatever men may think, and however they may act, still it is true that the use of ardent spirits, now so prevalent, is one of the greatest evils that has ever befallen the human race. It is a second curse, which seems destined completely to destroy every blossom of beauty and virtue, which the first left blanched and drooping here and there upon the face of the earth.

"*Dr. Cheyne.*—Ardent spirits are very destructive to health, and may be deemed a poison. Writers upon Toxicology include ardent spirits in the list of poisonous substances. I do not conceive ardent spirits necessary in circumstances of health. I have no doubt, if a man beginning at twenty, were to take one large glass of spirits regularly every day, he would thereby affect the duration of his life, probably abridging it by at least ten years. The subject has been before me all my life, and I think I am safe in saying so, supposing two ounces of spirits (one glass) were to be taken every day. I never knew a person who got into the habitual use of ardent spirits, whose moral character did not suffer in consequence. The entire abolition of ardent spirits would be a great blessing—the greatest blessing.

"*Dr. Ellis* declares that, medically speaking, the use of spirits is deleterious in itself, and carried to excess leads frequently to lunacy. The use of fermented liquors, and particularly of spirits, is very conducive indeed to bringing on lunacy; it first of all acts on the stomach, then on the nervous system; it brings on diseased action, disorganization of the brain is the consequence, and all the dreadful results of insanity follow. If persons have been in the habit of drinking beer only, the effects are much sooner got the better of; abstinence from the taking of the liquor, and good management in the open air, and employment, very soon restore the tone of the stomach. In cases of drunkenness from spirits, where the nervous system

has got much deranged, it is often impossible to effect a cure. Out of 28 cases, admitted last year into the County Lunatic Asylum of Middlesex, reported as recent cases, 19 were drunkards, five of whom were females, the oldest not more than 36 years of age. The health of those who are insane from drunkenness is worse than those from other causes, and the proportion of deaths much greater. Persons becoming insane from habitual drunkenness retain the disposition to drink; in the Asylum at Hanwell half the cry is they can get no spirits. They sadly relapse when recovered from insanity. We had a melancholy case the other day, who had been with us and was cured, but he took to drinking again and stabbed a policeman.

—

MEDICAL SESSION OF 1834—1835.

ONE of our contemporaries has taken the trouble of abusing, in no measured terms, the present system of medical education in this kingdom, "the fraudulent ticket and certificate system," which by-the-by, is the same in all other countries in which medicine is cultivated. The remedy proposed for this fictitious evil is, that every surgeon should educate his apprentice, and qualify him for examination before the Royal College of Surgeons, and Society of Apothecaries. Now, it appears to us, that this intended compliment to surgeons is somewhat like what the world designates a French one. The writer well knows, that there never was, nor ever will be, a physician or surgeon so perfectly acquainted with the medical sciences as to pretend to teach the whole of them. We request our readers only to reflect upon the proposal, that a physician or surgeon could pretend or attempt to teach anatomy, physiology, pathology, therapeutics, including chemistry, materia medica, botany, obstetrics, practice of medicine, surgery, and medical jurisprudence. Universities and colleges have been so stupid in all countries as

to decide that there ought and should be a distinct professor of each of these sciences; but it seems they were in error. The object of the French compliment is however very obvious; we are really surprised that it was paid from so intelligent a quarter, as we feel thoroughly convinced that there is not a surgeon in the world who could be so presumptuous and insane as to imagine that he could teach efficiently the whole of the medical sciences. Such was the opinion of every well informed physician, surgeon, and apothecary of England, Ireland, and Scotland, who was examined before the Medical Committee of the House of Commons; but according to the gratuitous assertion of our sagacious contemporary, they erred egregiously.

But let us suppose that all medical schools were closed, that surgeons alone—for the physicians are totally proscribed—were to educate their apprentices; and then consider the proportion of these that could pass the examining boards. In our opinion not one in ten thousand would be approved of, or receive a diploma or licence.

It further appears to us that the said supposed pantophysiological surgeon could not be in practice, if he attempted to deliver proper instruction in anatomy, chemistry, materia medica, surgery, obstetrics, &c. &c., as six ordinary individuals are occupied in diffusing medical instruction according to the present system of modern education, and for three winters and two summers according to present regulations.

Verily the individual who would attempt this must be an ultra-radical reformer. Unfortunately for him, a knowledge of the science and practice of the healing art cannot be communicated, either by the power of steam-engines, or even balloons; and until it can, we fear the present system must remain unaltered.

—o—

THE MEDICAL PROFESSION AS IT IS,
AND AS IT OUGHT TO BE.

Mr. Dermott's Fifth Letter to George James Guthrie, Esq.

DEAR SIR—My last letter contained observations upon the inutility and some of the evil tendencies of enforcing a knowledge of the *dead languages*, and upon the spurious type of education supported, and artfully kept up, by the aristocracy in our national (non-national) institutions. We will now, if you please, continue our consideration of the opinions expressed by you regarding private schools of medicine. I have, you recollect, already replied in my former letters to the following assertions, amongst others, of yours:—That the medical community at large (the main bulk of which is composed of general practitioners, *i. e.* those who have passed both the College of Surgeons and Apothecaries' Hall), should not be electors of their governing body—that the general practitioners should never be elected members of the council or governing body—that surgeons unconnected with an hospital cannot teach anatomy properly—that private lecturers do not teach so well as those in hospital—that in proportion as their fees are less, so they give less information, and that it is in the same ratio inferior in quality. As to the validity or invalidity of these positions which you have advanced, or of my remarks in refutation of them, we must leave that to be decided by the tribunal of *public opinion*.

But to proceed. It was asserted by you, in your evidence, *that a teacher cannot render justice to his pupils, and properly qualify them, unless he is provided with a museum, costing at least 500*l.* or 1,000*l.**

You well know that this expense is beyond the reach of most private teachers. I will moreover meet this, which I conceive to be a mis-statement, by asserting that *preparations of the bones*, showing their growth, &c., are certainly absolutely necessary; but dried preparations of muscles, vessels, nerves, &c., neither teach the exact relative position, nor the natural appearance of parts; they are therefore of little or no use to the lecturer, but for show, when he is furnished with a good recent dissection of the parts he is teaching. All the more frequent variations in the distribution of vessels are met with in the course of a single winter season, provided the class has such a moderate supply of dissections as the Anatomy Bill does at present, and should, in justice, render; and a much better judgment can be formed of these variations in a recent state than in a dried and varnished.

A few *morbid preparations*, exhibiting the leading principles in pathology, and a few on *comparative anatomy*, may be of use to the anatomical teacher; but a course of anatomy

and physiology has hitherto only lasted three or four months: and, during such a short space of time, it was morally impossible that any teacher could extensively and efficiently enter into either pathology or comparative anatomy. The most eligible place for a museum of morbid preparations is at the hospital whence they were procured—where the morbid appearances can be connected with the symptoms as detailed in the case-book, and where clinical lectures should be (and should have been) regularly given, in connexion with the exhibition of those morbid preparations. *No hospital should be recognised as a fit place for the instruction of pupils, unless clinical lectures are regularly delivered in the institution, conjoined with a reference to preparations, the history of which would then be well known.* Collecting morbid preparations in this way at hospitals would not interfere with the decent interment of patients dying in those establishments, and consequently not with the prejudices of the less-informed portion of the community.

It was certainly a very broad mistake, when you stated that the lectures in the metropolis had of late years undergone a deterioration in consequence of the private teachers increasing in number. On the contrary, it can be truly stated, that at no former period have the lecturers taken such pains with the pupils in giving them so much public and private practical instruction, or combined so much physiology, surgery, or even pathology, with their anatomy, as at present, and this, I maintain, is principally in consequence of the good example of the private schools, and the competition thus necessarily produced between the public schools and the private. I believe I had the honour of being the first to adopt the combination of private instruction and examination over the *recent subject*, in addition to my regular lectures; and in consequence of the practical help which it afforded to really industrious students, the public teachers found themselves obliged to adopt the same measures, for which perhaps some may not feel very thankful, inasmuch as it gives them more trouble.

In support of your assertion regarding the inferiority of private schools, and the absolute necessity of having a very extensive and costly museum, you say in your evidence, "A young man presents himself before us, and questions are put to him in minute anatomy; for instance I will take the kidney. He will be desired to describe its structure, and the manner in which the secretion of urine takes place. He hesitates, and cannot answer. He is asked, 'Have you had the structure explained to you by your teacher of anatomy?' He says 'No, I never heard a word of structure.' 'Well, but you have seen the preparation of it in the museum?' 'No, sir, we have no such preparation in the museum.' 'Have you

any museum at all?" "Yes, we have a few preparations."

Pray, then, my dear Sir, do you mean to state that all those pupils deficient in minute structure come from the private schools, or that more lacking such knowledge are produced by the latter than from the public ones? If so, I must demand your proofs; the *assertion* having been advanced, in justice to the private schools, they should be produced. Even admitting there are no wet preparations of the kidney in a museum, most of my ordinary injections of that viscus, as seen by sections of it made in the dissecting room, run as minutely as most of yours in your pickled preparations. Which are best—mine in a recent state, or yours in bottle?

The *assertion*, or *insinuation*, that private teachers, as a body, skip over structural anatomy, is, as you must see upon further consideration, most unjust; but, at the same time (as we know that such an assertion cannot call for its support a single proof), it is most laughable and harmless. If structural anatomy is improperly skimmed over in some places more than others, I verily believe, from the testimony of many, that those places are some of the public schools; for instance, the latter terminated their present summer course early in July (therefore it was only an apology for a course), whilst the private schools honestly continued theirs to the latter end of August; and this, too, recollect, when more came from the country to attend lectures than during any preceding summer, specifically in consequence of the last regulations of the Apothecaries' Company. If the instruction at private schools is so inferior, why do pupils come from other schools to ours, to see our dissections, and hear our lectures, even when threats and remonstrances have been held over them by some of the lecturers at Bartholomew's Hospital, and by others, for so doing? Is it to be crammed? No; and you know that too, yourself; for I have been obliged to you, my dear sir, for many pupils by your direct recommendation.

You are, in some respects, like Pitt and Peel, for the flexible plausibility of your tongue enables you to turn anything to make it subservient to the temporary support of your argument, however bad the cause in which the argument is used; and the most artful part of your evidence was when, assuming an air of generosity, you stated, that as a *proof* of the liberal feeling which you and your conservative brethren of the council possessed towards the private schools, one gentleman who had just commenced as a private teacher, in Westminster, would be fully recognised the next winter, as you had no doubt that the said gentleman (Mr. Dobson) would "get up" a museum in his school by the next October. Now, I full well know that Mr. Dobson could lecture more scientifically with a single dissection than many other men could with

the aid of that and a thousand preparations besides. But you know, too, that there was then an understanding between yourself and Mr. Dobson, that his school should be in alliance with the Westminster Hospital, and that it should be *bona fide* the school of that hospital.

The farce of "getting up" museums according to the present mode, is nothing else than the scrambling together of as many parts as possible, it matters not what, from the dissecting room—

"Here *muscles* lay, most reverently stale,
Beside the tortoise with a coat o' mail."

And all this for the purpose of throwing out a bait to pupils, without, of course, knowing anything of the history of most of the morbid preparations. This trickery is analogous to the quackish exhibition of useless coloured fluids in a druggist's shop; in a dark night, however, these do prove of some use, for they are shop-signs which tell the multitude where drugs can be procured.

I have already stated, that when a course of lectures lasted only three or four months, there was not sufficient time allotted for any lecturer to enter into pathology and comparative anatomy, and, I would add, not even to do justice to human anatomy or physiology*.

As to the non-establishment of regular courses of comparative anatomy, for the attendance of pupils, who is to blame (if blame is to be attached to any persons) but the council of the college? Certainly not the teachers of human anatomy.

You, my dear sir, are liable to make mistakes, like all other talented men who think, speak, and act quickly. It was another *very broad mistake* to assert that the college had not power to institute fresh and proper regulations, as *proved* by some of their coercive bye-laws issued by them by virtue of their charter—one of which, regarding the non-recognition of any teachers, excepting those connected with hospitals, I have already alluded to in the commencement of my second letter.

In extenuation of these sins of omission (i. e. not having issued, as you state, a sufficiency of salutary regulations), you dropped, my dear sir, a most unlucky expression.—"Give us power," (you say to our chairman, Mr. Warburton) "and we will be as despotic as you please." It was something like the Newcastle expression (as applied to the right of the hereditary-privi-

* The course has very lately been prolonged to six or seven months, which will give the lecturer more time to do justice to his pupils. This fact should, however, be known to all pupils, for reasons stated in my letter of last week, although the insertion of that letter was refused in the *Lancet*, certainly not in consequence of inutility.

leged abusing the consciences of others), "Cannot a man do what he likes with his own?" But I must say it was not in correspondence with the impartiality which you always exercise, as far as my experience goes, in your examination of pupils from private schools.

In reference to your expression last alluded to, some persons more malignantly disposed than myself may say, "By these words shalt thou be judged, and out of thine own mouth will I condemn thee." You, conservatives, have yet to learn the first rudiments of politics as received by the political age in which we live; that coercion and despotism are incompatible with the spirit of the present age; that such expressions must necessarily be contemptuously spurned by the enlightened and talented medical community in England, although they might well have suited the dark ages of gothic night, when the feudal system prevailed, of which we now only see, thank God, the crumbling ruins in the form of obsolete institutions.

It is a fact, my dear sir, and the expression of yours last mentioned is sufficient to confirm it, that all the members of conservative corporations are found, upon investigation, to be perfectly blinded by their individual interests, and perfectly insensible to the intellectual and political condition of society—they are in this sense "a century behind the times," they are all going to *Gravesend by steam!*

Believe me, my dear Sir,

Your obedient Servant,

G. D. DERMOTT.

DUPUYTREN'S CLINIC.

Hernia.—We have already reported several cases of strangulated hernia, in some of which the operation had a favourable, and in others an unfortunate result. Very lately*, in particular, we detailed three remarkable cases which occurred at the Hôtel Dieu, and took the opportunity of carefully describing the mode in which M. Dupuytren proceeds, in the liberation of strangulated hernia, both in the male and female subject. We pointed out the rapid success obtained, in one of these instances, in which recourse was had to union by the first intention. It is by concentrating our attention on whatever particulars of importance each case may present, and by neglecting all fastidious and unimportant details, that the greatest services are to be rendered to science. A lengthy case, diffusely described, teaches nothing; while its salient points, depicted in a few lines, will facilitate comparisons with other cases, and may thus become of great value.

A new operation for hernia has lately been

employed by M. Sanson; and to one particularity of it we would especially direct attention. A woman fifty years of age had been subject to hernia for twelve months. She was brought into the hospital with this hernia strangulated; in which state it had been for eight days, after having being engorged for eight days previously. The bowels had not been opened for fifteen days. It was a femoral hernia of small size; and all the symptoms of strangulation existed; such as hicough, nausea, vomiting, &c. M. Sanson performed the operation on the day of her admission. An incision having been made through the integuments, the other coverings were divided layer by layer, until the sac was reached. It was found to be injected, thickened, and of a fleshy appearance. On incising it, several drops of serous fluid escaped; and a knuckle of intestine appeared, two inches and a half in length, partly enveloped in the mesentery. Both of these parts were black, strongly injected, and adherent. In breaking through the union which existed between the intestines and the mesentery, a little blood was poured out. The stricture was divided directly upwards, and the intestine was pulled a little outwards. A white circle was perceived round the part which had been constricted. The intestine was very much thickened; but was not considered in so bad a state as to contra-indicate its reduction. It was therefore, with some difficulty, returned into the abdomen.

After the operation a considerable quantity of serous fluid was discharged from the abdomen; but two hours afterwards, the patient had a passage from the bowels, without the use of medicine or injection. On the following day she was in a satisfactory state; the abdomen being soft, with very little pain on pressure, and no fever. The nausea, vomiting, and hicough, had entirely ceased. Nevertheless, the continued serous discharge (the certain index, according to M. Dupuytren, of a *dropsical irritation*) seemed to him to presage an attack of peritonitis; or, if we please, an *inflammatory irritation*. The numerous experiments which the professor has made, and the observation of what occurs after injection for hydrocele, has led him to the conclusion, that whenever a liquid, or any irritating substance whatever, is placed in immediate contact with a serous membrane, the first exciting or inflammatory effect which it produces, is a secretion of serum. In hydrocele, for instance, immediately after the operation, when the fluid which the sac contained, as well as the fluid injected, is completely evacuated, the serotal tumour disappears, and unless the case be complicated, the testicle has ordinarily its natural volume. The next day the tumefaction returns; and the scrotum regains nearly the same volume which it had before the operation. The inflammation then leaves the testicle and its envelopes; the serous fluid is re-absorbed; and the cure is complete.

* See the London Medical and Surgical Journal, No. 181, vol. 7, page 794.

It is to a new serous effusion that M. Dupuytren attributes the temporary return of the scrotal tumour to its former size. And that which takes place in the tunica vaginalis, also takes place in the peritoneal sac; and whenever after the operation for hernia, a considerable quantity of serous matter flows out, we have to dread a fatal inflammation of the peritoneum, or of the intestines. In the present case these forebodings were justified by the event. The woman was seized with abdominal tension and pain; the vomiting returned, the skin became cold; the pulse small and frequent; and the weakness very great. Emollients, both external and internal venesection, three applications of numerous leeches to the abdomen, and afterwards revulsives were tried without success; and the patient expired on the fourth day after the operation. It was designed to effect union by the first intention; but no adhesion took place.

When the body was examined, the abdomen appeared moderately inflated; and on opening it, the peritoneum was found intensely inflamed, with a great quantity of sero-purulent matter in both iliac fossæ. That part of the intestine which had been included in the hernia, was of a blackish brown colour, and presented the white circle we have before indicated. The inflammation extended for some inches in the interior of the intestinal tube.

EPIDEMIC FEVER ACCOMPANIED WITH TETANIC SPASMS.

IN the years 1596 and 1597, a febrile epidemic prevailed in the Bishopric of Cologne, in Westphalia, in the countries of Waldeck and Wittenstein, and in Hesse which was vulgarly called Kriebel-krankheit, Kriempfsucht, or Ziehende Seuche.

It commenced with twitching and a sense of numbness in the hands and feet, sometimes on one side, sometimes on both. Soon after the patient was suddenly seized with convulsions, at first affecting the fingers of the hands and feet, and afterwards the arms, legs, shoulders, hips, and the whole body, which was either coiled up like a globe or stiffly extended. These convulsions were attended with extreme pain, which forced the sufferer to cry aloud. Vomiting in some cases attended the first invasion of the disease. If appropriate medicines were used, the affection did not reach the head for several days or even weeks; but if these were neglected, the head also was attacked; in which case some patients were seized with epilepsy, and after the fit lay as if they had

been dead for six or eight hours; others were affected with coma or delirium, which lasted four days or longer, and was followed by impaired sight or hearing, or even by paralysis. On the cessation of the paroxysm the patient experienced a most immoderate desire for food. Diarrhœa afterwards supervened, and in most cases the hands and feet swelled, or there was an eruption of bullæ: sweating never occurred. This disease was contagious, and the latest period of the contagion extended often to six months and sometimes to twelve. (Sennert. Lib. De Febribus Epitome lib. iv. c. 16.) The author attributes this curious epidemy to pestilential ichors arising from unwholesome food in a time of scarcity, and affecting chiefly the brain and nerves. The disease was dangerous and intractable; those patients who were epileptic seldom lost the tendency to that disorder; those who were delirious remained stupid: some patients experienced a recurrence of the disease in some degree every year, in the months of December and January. The cure consisted in the evacuation of the depraved humours and the corroboration of the brain and nerves, the former by purgatives, the latter by antispasmodics and cordials, which two classes of medicines required to be alternated. The disease above described seems to have been an epidemic form of the *Raphania* so called by Linnæus from its being supposed to arise from the seeds of the *Rhaphanus Raphanistrum* being mixed with the corn. The *Raphania* or *morbus cerealis*, is said not to be uncommon in Germany and Sweden.

TYPHUS FEVER OF THE OLDER ENGLISH WRITERS.

THE typhus of the present day has by the operation of a variety of causes, become so changed from the putrid fever of the older English writers, that they appear like two perfectly distinct diseases; yet there is no doubt of their identity, and the comparison should teach us to be cautious how we regard any particular symptoms or pathological conditions as *essential* to fever, since what appears characteristic of the fever of one age, is entirely wanting in that of another. The following is a very striking case of putrid fever described by Huxham, who believes it to have been the most severe from which any person ever recovered.

"An eminent surgeon of a neighbouring town, of a thin and somewhat tender constitution, but constantly used to action and exercise, and frequently subject to fevers and scorbutic rheumatisms, from taking cold, &c., in October, 1741, fell into a kind of slow fever, attended with slight rigors, frequent flushes of heat, a quick weak pulse, loss of strength and appetite, with a great load at his breast, and a heavy sort of respiration. Notwithstanding this, he continued in his business, constantly riding and fatiguing himself for four or five days after this seizure. I met him at a gentleman's house, who was my patient; and finding him as above, and that his breath was even then very offensive, I earnestly desired him to take timely and due care of himself. Two days after, he being at a gentleman's in the neighbourhood, was taken all on a sudden with a very great faintness, and fell off his chair. Upon lifting him up, the company observed several livid and violet-coloured spots on his arms and neck. It was with great difficulty they got him home, though but two or three miles distance, he very frequently fainting by the way. The disorder increased every moment; he had vast langour, with pain and extreme oppression on the præcordia, and a perpetual sighing; his breath now stank abominably, and a fœtid bloody matter leaked continually from his gums, and thousands of livid, violet, and black spots appeared all over his body, on the trunk, as well as the limbs.

"He was bled to about $\frac{3}{4}$ xii from his arm, but this gave him no manner of relief, the oppression, sighing, fainting, and anxiety, continued as bad as ever, nay rather increasing; a violent hæmorrhage also broke forth from his nose, which continued from both nostrils; he was bled again to $\frac{3}{4}$ x about twelve hours after the former bleeding: neither did this give him any relief, but increased his weakness considerably, and he continued as anxious, restless, and oppressed as ever, without even the least sleep. The blood now not only issued from his gums and nose, but he also coughed up blood; indeed the bleeding from his nose had ceased somewhat, but it increased from his gums, and in a surprising manner blood now likewise dropped, though slowly, from the caruncle of one of his eyes; and several livid pustules on his tongue and withinside his lips, broke, and discharged a bloody, thin matter very copiously.

"The hæmorrhage being somewhat restrained, a bloody dysentery came on with severe gripes, and excessive faintness, and he was still exceedingly restless and very feverish: his pulse now intermitted every sixth or eight pulsation, and then fluttered on again vastly quick; he had likewise a constant tremor and subsultus. The hæmorrhage all this while continued from one part or other, and when stopped at one place, forthwith burst out at another; so that his

urine now seemed tinged with blood, being very dark-coloured, nay almost black. Soon after he was bled the second time, I was sent for, and hastened to him. I found him in the manner described, under an inexpressible anxiety, yet quite free from delirium, though he had no manner of sleep for several days and nights; his tongue was vastly black, and his breath so insufferably stinking, that it was greatly offensive even at a considerable distance; and his stools were so horribly nauseous and fœtid, that the very nurses fell into vomitings and faintness in carrying them off.

"I found that neither of the portions of the blood that had been drawn (not even the first) had separated into crassamentum and serum as usual, though the former had stood so many hours; but continued as it were half coagulated, and of a bluish livid colour on the top; it was most easily divided by the slightest touch, and seemed a purulent sanies rather than blood, with a kind of sooty powder at bottom. His hæmorrhage still continued, especially from the tongue, lips, and gums, with a perpetual dripping of thin bloody ichor from his nose; so that he was reduced to an extreme degree of weakness, with never-ceasing tremblings, subsultus tendinum, and almost continual faintings.

"What was to be done in this dreadful case? Would the hot, alexipharmac, volatile cordials and blisters have served him, as some might have imagined, considering his extreme weakness, faintings, load on the præcordia, tremblings, &c. But would they not have been certainly deleterious, would they not have certainly killed him? as they would have added to the stimulating acrimony, increased the fever, and further destroyed the crisis of the blood, already nearly quite dissolved, and reduced to a kind of putrid gore.

"I took it in this view, and as I had experimentally and repeatedly known the great use of the bark in preventing and stopping the advance of gangrenes, I gave him frequently of it in small doses with elixir vitrioli, premising a small quantity of rhubarb. Besides this he drank tincture of roses, with cinnamon water made very acid, and also a decoction of Seville orange rind, red roses, cinnamon, and a little Japan earth (as it is called) well acidulated; claret and red port, with about half water, he drank at pleasure. As the bark sat easy with him, I continued its use, and increased its quantity, giving with it some confect. fricast. sine melle to restrain the dysenteric flux; and yet I now and then interposed a small dose of rhubarb, to carry off any bloody, bilious, or sanious matter that might be lodged in, or leak into the intestines. In the mean time I ordered him to be frequently supported with rice, panado, sago, jellies of harts-horn well acidulated, toast out of claret or red port wine; and I

directed fomentations of aromatics and astringents, boiled in red wine, to be frequently applied to the whole abdomen.

"By this method, steadily persisted in, was this poor gentleman, through divine goodness, raised from a state of universal rottenness, as it were, to perfect health: not but that, for a very considerable time after his fever was quite gone off, he continued extremely weak; and even after he was capable of walking abroad, the hemorrhage from his nose would return on the least occasion, his gums would bleed on the slightest rubbing, and his breath continued very offensive for a long time. By the further use of the cortex, elix. vitrioli, &c., this also entirely ceased; but his legs and feet continued very much swollen for a much longer time, and his flesh all over the whole body remained exceedingly soft, tender, and sore, scarce bearing the least touch. Rhabarbarate purges, easy stomachic chalybeates, elixir of vitriol, pyrmont water with proper diuretics, and gentle regular exercise, at length carried off all those symptoms; and in about two or three months he recovered a good state of health, which he still enjoys."

EASTERN MEDICAL ASSOCIATION.

WE are gratified to observe that a Meeting has recently taken place at Bury St. Edmunds, for the purpose of forming a Medical Benevolent Association. It embraces six of the adjoining counties. We sincerely wish many similar societies will be forthwith established, and that our brethren in the country will follow the example we set to them in the metropolis, of the profession at the commencement of a new Medical Session.

—o—

ROYAL ACADEMY OF MEDICINE IN PARIS.

WE feel much pleasure in informing our readers that Mr. Crosse, of Norwich has been elected a corresponding Member of the Royal Academy of Medicine in Paris, a compliment which he well deserves for the talent he has long displayed as a practical surgeon.

—o—

THE late Gilbert Thomas Burnett, Professor of Botany at King's College, and to the Apothecaries' Company, has left a Mother and a Sister in a state of utter destitution. It is well known to his professional friends that his life was shortened by his unceasing and laborious exertions for their support. Eulogies upon the dead are too often lavished indiscriminately to obtain in general much confidence; but of Gilbert Thomas Burnett it may be said, without the slightest exaggeration, that he was highly respected for

his talent, and most warmly esteemed for his moral worth and probity, by all who knew him. It is hoped—it is confidently believed—that this appeal to the public, and to the Members of the Medical Profession in particular, on behalf of his family, will secure to them at least a temporary rescue from their urgent distress.

Subscriptions are received at Sir Claude Scott's Bank, Cavendish Square; at Mr. Probert's, 6, New Cavendish Street; and at Mr. North's, 66, Upper Berkeley Street, Portman Square.

PUBLICATION OF THIS JOURNAL.

IN reply to several correspondents from different parts of the kingdom, complaining of irregularity in the receipt of this Journal, we beg to state, that it is published every Friday at twelve o'clock (the same time as the *Lancet*), and that there is no reason why it should not be received at the same time as our contemporary. We shall at all times feel much obliged for private communications of this kind, and shall use every effort to trace the source of irregularity, which we assure our friends, does not rest with our publisher.

—o—

-BOOKS.

IN the press, and will be published early in October, Principles and Practice of Surgery, founded on the most extensive Hospital and Private Practice, during a period of nearly fifty years. By Sir Astley Cooper, Bart., F. R. S., House Surgeon to the King, formerly Lecturer on Anatomy and Surgery at Guy's and St. Thomas's Hospitals, now Consulting Surgeon at Guy's. Edited by Alexander Lee, M. A., M. D., &c., &c.

A Third Edition of Dr. Castle's Introduction to Medical Botany, greatly enlarged and improved, illustrated with plates.

On the Diseases of Women and Children. By James Blundell, M. D., to which will be added, Notes and illustrations, by Thomas Castle, M. D., F. L. S., &c. &c.

The Obstetrician's Vade-Mecum, or Aphorisms on the Application and Use of the Forceps and Vectis; on Preternatural Labours; on Labours attended with Hemorrhage, and with Convulsions, &c. &c. Illustrated with Sixteen Plates. Ninth Edition; with a Portrait of the Author. By Thomas Denman, M. D., Licentiate in Midwifery, of the College of Physicians London, and Honorary Member of the Royal Medical Society, at Edinburgh; considerably augmented and adapted to the present state of Obstetrics, by Michael Ryan, M. D., Member of the Royal College of Physicians, London, Professor of Medicine and Obstetrics, at the Medical School, Gerrard-street, Soho-square, &c. &c.

SELECT LECTURES,

FROM

M. BROUSSAIS'

*Course of General Pathology and Therapeutics;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE XVII.

Transmission of Irritation as a cause of Gastro-Enteritis—Gastritis.

As yet I have only mentioned in a general manner the transmission of irritation as a cause of gastro-intestinal inflammations; but it is a question that requires to be treated of more in detail. It is well known that on all occasions of the development of an inflamed point in the system, were it only consequent on a slight wound, incision, or operation—bleeding for instance—a disturbance in the system may supervene, which disturbance is an irritation. Those organs that possess the most nerves feel it the first; and the foremost is the brain, but it resists inflammation much more than others. In order to avoid the admission of the great frequency of gastro-enteritis, an encephalitis, disguised under the name of cerebral fever, was had recourse to not very long ago; but after some time the subterfuge was perceived to be untenable, and the name of dothientery was substituted—a matter that I shall explain at a subsequent period; meantime, let us rest upon the leading fact, that when irritation is developed in a point to a certain degree, it disturbs the nervous system of all the viscera, disposing them to sanguineous congestions; for instance, a man in good health undergoes the operation of lithotomy, before which he had no phlegmasia; three or four days after the operation—and it implicates parts that are in close approximation to other viscera—fever appears, and a gastro-enteritis or peritonitis comes on, under which the man sinks. Now, what takes place in all this? the dragged, lacerated, contused organ has transmitted the irritation to the entire nervous system; various organs feeling more acutely than usual, become congested, and more or fewer of them pass into a state of inflammation, of which some are more susceptible

than the digestive apparatus. But wherefore it more than another, you will ask; are not the lungs as sanguineous as it? Yes, they are so, and even more so; but they are not so nervous, they are not strewed with the same fearful quantity of nervous papillæ, nor are they provided with so considerable a ganglionic nervous system as the stomach, not to mention the multitudinous ramifications proceeding from the pneumo-gastric nerve. Indeed, this nervous predominance of the stomach would appear to be indispensable to the powerful motive that urges the animal to seek nutriment. It is therefore necessary that you should be fully convinced of this arrangement, and of the important part which, through it, the digestive canal plays; and this not only because it enables you to comprehend the frequency of its inflammations, but because it is upon it that you are bound to act in the treatment of disease; in fact, the apparatus in question, like a beggar, is ever calling out, "Give a potion, that I may imbibe it."

In summing up, we may say that when a phlegmasia occurs in any part of the body that is not the digestive canal, it is frequently the fate of the latter to suffer the most, and if it be inclined to inflammation, it is sure to fall into it. Here then we have a very essential cause to be borne in mind, with regard to irritations of the digestive canal. Subsequently, these irritations degenerate or not into inflammations, according to circumstances, predispositions, and the manner in which they are managed. I do not maintain, as some stupid people have said, that a contusion or wound always induces a gastritis; but I assert that if either be to any great extent, an irritation of the nervous apparatus ensues that is communicated to the gastric organs, which being more nervous than others, suffer more from it, and may be exalted to various degrees up to that of inflammation. In the slighter shades you may call this diathesis or what you please; but when an actual gastritis ensues, you must express yourselves in other terms.

So far, then, I think I have sufficiently laid down the idea I have of the manner in which inflammations of the digestive canal are formed: I might point out further pe-

cularities in the process, but such will be found in the particular history of the phlegmasiæ of each organ. Enter we therefore now into details, and first of all we will speak of those of the superior portion of the canal. Here however a difficulty presents itself; namely, that one region is seldom alone affected. To this I say, that we can always judge whether it is so in a predominant degree; do not therefore construe too rigorously all the expressions I use, nor when I speak of gastritis, believe that I assert the impossibility of duodenitis, jejunitis, or ileitis being accompaniments of it. Pay attention to the leading phenomenon, in order that by putting an end to it, the others may also disappear. I begin with the gastric region, where I shall first exhibit inflammation in its acute stage.

Gastritis.—Its specific causes are the most exciting of all, and they consist in strong mental emotions, and in the most heating aliments, and the most stimulating drinks. Almost always the stomach, the duodenum, and their appendages are the first to receive the influence of these causes and suffer therefrom. Here too I might mention poisons, and corrosive and burning substances, alcoholic liquors in excessive quantity, various mineral salts, that are capable of effecting a chemical inroad on the gastric mucous membrane; but I shall leave these substances that have specific properties to stand over to the section on poisoning.

The development of gastritis manifestly exhibits two forms, one slow, the other sudden; the former is less known than the latter, because in the progress of science, the most prominent objects are the first to be recognized. Were a man seized with gastritis after swallowing liquid chlorine, rectified alcohol, an acid, or arsenic, it would be readily detected, and admitted without hesitation. The onset would be rapid, acute pains would be felt at the region of the stomach, and increased by pressure; there would be a burning feel in the throat and mouth, it would be painful to swallow at all; the mildest fluids would fall as if on a denuded portion of the skin; sometimes they induce vomiting, like the most irritating drinks: in a somewhat slighter degree water may be retained, but will still cause an uncomfortable sensation, would augment the malaise, the inquietude, the sinister presentiments, and the prostration of the powers of the patient—in this shade gastritis is recognizable by every one: look to the following.

There are some persons who live sumptuously, who eat and drink beyond their wants, add refined processes to the joys of the table, and soon begin to have an increased appetite. Towards the close of their digestion they have a dragging at the stomach, which drives them to a closer approximation of meals; they eat eagerly, satisfy themselves, and are for a time easy. Meantime

they begin to have head-aches, burning at the stomach, and flushes of heat, which disappear after digestion is finished, and the appetite again comes on, accompanied with the same draggings of the now empty stomach. To such persons you may predict the accession of a gastritis, unless they change their mode of life. In fact, if they persevere in it the heat of the stomach no longer ceases with the end of digestion; they no longer feel the necessity of having recourse to aliments; the appetite fails; the gastric ardor becomes permanent; a dry heat of the throat supervenes, with violent and continued pains of the head, and to these are added complete lassitude of the limbs, and total loss of all desire for food. In such a state of predisposition it is that the acute state takes possession of them, and its incipient period is of varied duration. The individuals affected may ward it off for a time by some attention to diet, and by cooling drinks; but when once the predisposition is established, it is very difficult to destroy it by these precautions alone. Let them starve for a week, and then commit the smallest excess, it suffices to cause gastritis. In the gradations through which they pass they may become stationary at a latent point of super-excitement, constituting a shade of chronic gastritis, of which we shall have occasion afterwards to speak.

The disease arrived at the acute stage, the heat augments, the ingesta are vomited: his sufferings are so intense after taking food that the patient refuses to drink, and of course, to eat; thirst takes the place of hunger, and it ultimately is insatiable, for the stomach presently rejects even the lightest drinks; at the same time an excruciating pain, accompanied with inexpressible anxiety and malaise, is referred not only to the epigastrium but to the entire anterior and inferior half of the chest, as high as between the breasts; the whole centre of the trunk is the seat of a burning, furnace-like heat, and this sensation is the more decided as the inflammation frequently rises several inches into the esophagus: the skin over this region is tender and hotter than the rest of the body, as both the patient and the observer know. In the onset he has a feeling of cold, though there be increase of heat; the tongue is contracted, sharp, always red in the first degree: at a later period it becomes flatter and loses its redness, in consequence of the exhaustion of the sympathy. If the mouth be widely opened, a redness of the pharynx and a swollen condition of the mucous follicles at the root of the tongue may be observed. At the same time the pulse is frequent, the head painful, and there is a sense of extreme debility and prostration. Here again we have a very well marked and recognizable gastritis.

Let us now observe it in its highest shade of development, which is the sporadic

cholera morbus; the epidemic will be examined apart. The common cholera presents the following aspect: excessive pains of the region of the stomach, vomiting of ingesta, fatigue, exhaustion, and contraction of the muscles, particularly of the calves of the legs; frequently purging, shewing the participation of the lower end of the digestive canal in the irritation; after the vomiting has continued for some time, the pulse becomes small and weak, the extremities turn cold, the countenance loses all lustre, the eye-balls sink, the temples fall in, the patient seems nearly dead, and resembles a mummy. The weakness and smallness of the pulse here remarked is not a phenomenon altogether peculiar to cholera; all violent phlegmasiæ of the abdomen that are accompanied with pains affect the heart's movements, diminish its impelling force, and thus produce coldness of the extremities. This form of gastritis has not always been placed with the phlegmasiæ, because it paralyzes the circulation, and because people are in the habit of taking phlegmon as the type of inflammation. Some, looking to the nervous phenomena, have made it a neurosis; others, paying all attention to the evacuations of bile, make it a bilious disorder, according to the literal sense of the name it has. For me, I consider it to be a gastro-intestinal inflammation, with exaltation of the sensibility of the nervous papillæ of the digestive canal, an exaltation that becomes general and disturbs innervation. This innervation gives the first sign of disorder in the convulsions of the membranes; subsequently, it is diminished and interrupted by the implication of the heart, which becomes so weak that the patient dies asphyxiated, without a vestige of pulse. Such a case was brought to Val-de-Grâce a few days ago; the man was cold as marble, his eyes sunken; he was vomiting, and purged incessantly; we considered him as attacked with a gastro-enteritis having a choleric form, and we treated him with leeches; the vomiting ceased, but we were obliged for a whole fortnight to keep up revulsion to the external surface, in order to re-establish the circulation; at this moment his pulse is stronger than any in the ward.

The slackening of the circulation in cholera is not so mysterious a matter as some persons seem to think: it is the consequence of the racking and convulsive pain of the inflamed digestive canal. Some day or other this will be verified in exotic cholera, just as I have verified it in regard to our own. I maintain that in epidemics of gastritis and gastro-enteritis there are always some that go to the length of cholera; the most intense take place in predisposed nervous systems. Doubtlessly, when cholera attacks a great number of individuals, there must have been some more general cause than the predisposition to which I allude. The ac-

counts we have from Warsaw, Petersburg, Berlin, and other places, mention that drunkards were attacked before any others; and in some countries the disease only attacked those who were already in a state of gastric superexcitement. Behold, then, the connexion! it is of such a kind that you may readily comprehend that a gastritis being given, if it happens in one whose nervous sensibility is exalted by stimulation, it rises to the violence of cholera, and this the more easily as the temperature is hotter. Thus, the cholera is more common in hot than in temperate climates; but is this any reason why it should invariably diminish and cease as we approach northern latitudes? Assuredly not; for when heat ceases to stimulate, alcohol and other excitants are substituted; when people are deprived of the stimulus of a fine sky, they replace it by that of the internal and external parts. Men who are dedicated to science have less occasion for such, and on this score are less exposed and more happy than others, inasmuch as they find in intellectual excitement wherewithal to dispense with that obtained from drink; stimulus of some kind is absolutely necessary for life and the sense of life.

The cholera of these climes is with common consent allowed to have two different modes of proceeding; by one it causes death by the exceeding spasm, pain, and constrictions, in the space of from one to four days, and even a few hours—excessive inflammation of the stomach is rarely supported more than twenty-four or forty-eight hours. In less elevated shades, if well treated, a sudden cure may be obtained; if not, it changes into gastro-enteritis accompanied with violent re-action. Thus it is in epidemic cholera, and so I could have prophesied it would be.

After death by the most intense degree of sporadic cholera, the stomach and digestive tube are found shrunk and contracted, the mucous membrane red, inflamed, and frequently covered with a mucoso-purulent layer, with deep wrinkles, softening, and other disorders, which I shall describe in speaking of the inflammation that has pervaded the greater part of the tube; the pia mater and spinal cord injected, and the nerves more dense—I have seen the latter as resisting as tendons.

The prognosis of this affection is founded on the intensity of the disease, and the individual predisposition. You know very well that there are persons who live habitually with a shade of gastritis; these are the first to be seized in all epidemics whatever, and may be carried off in a few hours; in them there is no resource; they are dead before you can assist them. As to those who are more resisting, you may predict their fate by the pulse, the temperature of the body, and the state of the cerebral functions. If the blood no longer circulates in

the limbs, if cold prevails over the surface, and the senses are gone, you are no longer able to rescue them from danger. Those who remain in a medium shade, who vomit, retain their faculties and heat of the extremities, and in whom the pulse is not extinct, may almost all be saved.

The treatment has been much disputed. The ancients boldly gave water and acidulated drinks, in order, as they said, to dilute the acrid bile: modern classical practitioners imitate them: but after diluting this bile they give narcotics. The moderns have spoiled this precept by regarding the bilious evacuations as secondary only, and paying attention to the nerves alone: they give opium from the beginning, and forbid the diluents. In such as are able to stand this treatment there has been some success: but drinks are imperatively called for, and it is in vain that the physician forbids them. After a sedative which you consider to be very mild, the heat is felt more than ever, the thirst becomes irresistible, the patient turns restive, and you can no more prevent his drinking than you can a regiment passing by a river in the dog-days. Thus the patient becomes his own physician when he who advises is in error, and wishes him to struggle against his instinct. Those who use ether and other supposed sedatives of the same kind, heat and disgust their patients still more: if such treatment has not been fatal in the majority of instances, it is because the patients have slackened their thirst with cooling drinks in spite of all contrary orders. Not thus do physiological physicians proceed: they know that they have to deal with a predominating gastritis, with exaltation of the nervous sensibility of the stomach: consequently, if they reach the patient before the circulation is arrested, they immediately have recourse to antiphlogistics, to general bleeding if there is plethora, to local bleedings of the epigastrium, if the contrary is the case: they then use narcotics, ice, or the lightest cold drinks, in small quantity—and this treatment succeeds wonderfully. If the inflammation is not confined to the stomach, and extends into the digestive tube, they follow it up until it is extinguished.

After gastritis characterised by excessive sensibility of the stomach and intolerance of all ingesta, I have found this organ contracted, undilatable, reduced to the calibre of an intestine, and even unable to admit a finger, by the violence of the spasm. At this degree of intensity the disease ordinarily terminates in death, with violent evacuations, nervous and convulsive accidents, arrestation of the circulation, cold extremities, decomposed countenance, &c. Yet it is not impossible to see it end in resolution if the treatment be well managed; on this subject I told you that antiphlogistics were proper in the commencement, and

that, above all, it was necessary to be active with local bleedings.

Before proceeding further in the history of the acute inflammations of the upper portion of the alimentary tube, I must speak of the shade that depends on acrid, corrosive poisons: not that it differs essentially from that I have just described, but because it presents certain peculiarities, and furnishes several special indications. In the shade in question, the pain is more concentrated in the epigastric region, is excessively sharp, depresses the powers, takes away the strength of the limbs, and arrests the pulse: the vomiting is more incessant, and such is the exalted sensibility of the stomach, which is partly corroded, that it obstinately rejects everything as long as it has the power, and when it is lost the anguish increases, meteorismus comes on, the prostration of the powers is extreme, the patients fall into deep despair, and become convulsed. This shade, therefore, is specially characterized by the pain, which is of the most atrocious kind, and accompanied with a feeling of corrosion. Then come the commemorative signs, but these do not always appear. Men are sometimes brought to us who have swallowed brandy mixed with sulphuric acid, or pepper infused in brandy—a horribly burning draught: they frequently do not tell us the cause of their state, and of the excessive pain of the limbs: hence the necessity of not depending alone on the commemorative signs in forming a diagnosis, and of paying attention to the principal symptoms; and these are, as I told you before, the excessive pain, the imminence of peritonitis, and the extreme prostration, to which you may add the physical and chemical characters of the poisonous matters vomited.

Gastro-enteritis.—We now follow inflammation into a lower portion of the digestive canal. After commencing in the stomach, and staying there one or two days, it may extend into the duodenum and small intestines: it is then a gastro-enteritis, following on acute gastritis. It is generally difficult to determine *a priori*, when a patient comes with symptoms of gastritis, whether they will remain predominant, or diminish and give place to gastro-enteritis. What I now state is altogether of recent observation; the connexion between gastro-intestinal inflammations was formerly not at all understood. Like yourselves, I have paced the hospitals, and always considered that a gastritis could never be anything but a gastritis, an enteritis always an enteritis, and a dysentery always the same, having no idea that each of these might be transformed to the other: as long as I continued in this erroneous way of thinking I understood nothing of pathology. Need I repeat it? You must follow inflammation, step by step, in all the tissues it is capable of invading, and strive to recognize it by all the external signs that present them-

selves. If you persist in studying the histories of gastritis, enteritis, dysenteries, peritonitis, &c., and in isolating them, instead of being guided by this method, which associates and shews you them connected with each other, you will be under the necessity of substituting one disease for another, and only admitting it when it is found alone, that is to say, scarcely ever, you will have no knowledge of the pathological phenomena, and you will pass your lives in astonishment. But I say to you, study inflammation: look at it progressing, rising, descending, starting now to the right, again to the left: observe the action of modifiers, the manner of the patient's respiration, the changes in his digestive functions, the modifications of his morale, &c.: from all these you will draw your deductions, and medicine will then be a positive science in your hands. Guided by this method, you will say that inflammation, after pervading the stomach for two, four, or six days, so that you would imagine you had only to deal with an overwhelming gastritis, may cease in that organ and re-appear in the intestinal canal, so as quickly to change the aspect. In such case the patient has no longer so much thirst, or at least, if he has, he no longer vomits: he absorbs a much greater proportion of the fluids you give him, whence you may conclude there is no longer any constriction of the pylorus to stay their passage, the sensibility of the epigastrium diminishes, the central part of the abdomen becomes more prominent, meteorismus supervenes: if you strike the abdomen you find a resonance in those parts where there are not fecal matters, as remarked by M. Piorry: the patient does not suffer so much: the constriction and uneasiness are considerably lessened, and there is even a tendency to stupor: the pulse, previously contracted, fills out: the heat is spread uniformly over the surface: the tongue is as red as usual, but less contracted and moist: there is a greater development of fever, with exacerbation, each twenty-four hours. Remark that this group of symptoms may come on primarily without having been preceded by days of gastric irritation, or only after a few days, or even a few hours, of the latter. As for the pain on pressure, it is not well-marked—most frequently there is none: if, however, the disease recurs in one who has had it before, there will be some tenderness. Such is gastro-enteritis: further on I will mention the different denominations it has received: I only wish to picture its progress to you.

It is possible that, after a week or two of this state, you shall see the tongue expand, become more moist, the heat of the throat dissipate, the thirst cease, the stomach become quiet, the skin halitous, the urine, from being scanty and red, flow copiously and clear, the malaise disappear, some stercoral and bilious evacuations pass without

pain, the appetite return, and the patient request food: thus a cure is wrought.

It is possible that, instead of disappearing, it shall be followed by diarrhœa, after seven or eight days, and then the aspect is changed; that the diarrhœa is accompanied with pain; that all at once the pulse sinks; that the commencing moisture of the skin vanishes; that the latter becomes dry—not of that dryness that is manifested with excess of heat, but rather cold; that copious stools supervene, which cool the body, emaciate and sink the muscles, and which are followed by death in seven, ten, or fifteen days, or else by a chronic state, the appetite re-appearing. If the acute stage extends beyond this time the appetite does not return: delirium and subsultus come on, and the patient sinks, with the belly shrunk, and an extremely fetid diarrhœa. And what is the meaning of this? Why, that the inflammation has passed the ileo-cæcal valve, has extended into the large intestine, and has exhausted the patient by its excess, and by the abundance of the evacuations.

It is possible that, anterior to any other affection, the patient has, in consequence of bad regimen and digestion, had slight colics and purgings without any derangement of the appetite, and that subsequently a disturbance of the gastric functions supervenes: that suddenly the inflammation passes to the acute condition, seizes on the upper part of the canal, and suspends the evacuations: that then, after eight or ten days, the purging returns, followed by the symptoms I have already pointed out, and that it exhausts and kills the patient.

Now remark these three cases; diarrhœa preceding an acute gastritis, and stopping when the latter becomes predominant: diarrhœa continuing through the whole duration of the gastro-enteritis, and terminating fatally: diarrhœa succeeding gastro-enteritis, and ending variously. All this is possible: would you have me make of these possibilities so many groups of symptoms and particular and independent diseases; and is it not more convenient to study them as I do, and as nature presents them to us? But we have not come to the end: I will shew inflammation out of the mucous membrane, and disclose new possibilities.

It may, when predominant in the upper portion, act more especially on the brain, suddenly produce ataxic and adynamic phenomena, and kill the patient. It only requires for this effect a predisposition to encephalic irritation. Predominant in the middle portion, it may produce the same effects. If predominant in the lower portion, it will induce them less readily, because in that locality it is attended with evacuations which empty the vessels and prevent the congestion of the superior organs; and, moreover, because the nervous connexion between the great intestine and the brain

are more active than between the latter and the stomach, or small intestine.

Let us pause on these ataxic and adynamic phenomena, and in order to conceive of them, let us begin by calling to mind that all irritations of inflamed organs are referred to the encephalon and its prolongations, and thence spread throughout the nervous system. These converging stimulations irritate the cerebral substance, and give rise to the phenomena in question: this may be strictly proved whenever an inflammation exists in an influential organ of the economy; exasperate it, and you behold ataxic phenomena spring up; calm it, you see them disappear. This fact has been already observed in the inflammations of the exterior of the body, and you are the more likely to meet with it in those of internal organs; if you wish further confirmation of it, without having recourse to experiments that are only allowable in animals, follow the practice of the stimulating physicians, for *they* put no obstacle in the way of your seeing it. You will find that whenever a phlegmasia strongly influences the nervous centres, they become irritated, and may inflame, and that this more especially happens when inflammation has attained a high degree of intensity in the mucous membrane of the digestive canal. It is an eternal law established on innumerable facts, and so invariable, that I defy you to show me a man affected with disorganization of the villo-mucous lining of the canal in question, who has not at the same time some deterioration of the intellectual faculties; so much so, that without having recourse to manual examination, and from the manner alone in which the cerebral functions are fulfilled, I will tell you what condition that membrane is in, whether it is unchanged or altered, inflamed or softened, &c. Whenever, then, inflammation exists to great extent in the upper or middle portion of the digestive canal, be assured that disturbances in the functions of innervation will manifest themselves, and that you will have ataxy and adynamy, the former more in connexion with lesions of the superior, the second with those of the middle portions, and that they will be manifested by delirium, restlessness, subsultus, prostration of strength, coma, and convulsive movements of varied degrees according to the constitution of the individuals affected. So striking are these symptoms, that our hospital nurses, all ignorant as they are, when they tell us that a man with gastro-enteritis is delirious or not, is tranquil or restless, judge by that alone whether he is better or worse, and are far less under the cloud of error than many erudite doctors.

Inflammation may traverse the thickness of the digestive canal, and proceed to the peritoneum; this is seen in all periods of the disease, but more frequently when it

lasts a long time; sometimes it is observed from the very onset, and it only requires an ill-timed stimulation to cause it. At other times, in the space of fifteen to twenty days, but more frequently towards the close, after forty, fifty, or sixty, at a time when you think the disease on the point of being cured, when the pulse is diminished in frequency, the tongue moist, when you are full of hope, and the emaciated patient begins to smile, a perforation takes place, peritonitis supervenes, and in a few hours he is dead.

Another chance; the inflammation passes to the bladder in a given time, and you have dysuria. Do not imagine that when a patient cannot pass his urine, it is always owing to a cerebral congestion; it is the inflammation that has reached the bladder, and it may even reach the kidneys. I have seen most horrible nephritis, which I could only consider as an explosion of inflammation at, as it were, a tangent.

It may likewise invade the throat and larynx. In the highest degree of gastro-enteritis the tongue is always red, as well as the velum palati, and there is a feeling of constriction in the pharynx; the voice is grating and sepulchral; all the openings of the mucous membranes, which you behold to be red, and which you considered to be congested by a simple sympathetic influence, are in a veritable inflammatory condition; in these parts are included not only the mouth, the pharynx, the larynx, but also the extremity of the penis, and the vulva. M. Louis has verified the same views. It is the internal fire that seems to exhale by the gaps of the crater; the inflammation of the apertures of the mucous membranes is always in proportion to the internal inflammation. In the chronic stage this sympathy disappears.

The inflammation may be communicated to the lungs, and this is in some part explained by the similarity of tissue and the simultaneous application of the irritation. Long ago I remarked how irritation of the bronchial lining accompanies inflammation of the internal surfaces of the digestive canal, and that pulmonary congestions follow upon it, particularly in winter. You would be wrong to announce them as an essential accompaniment, or as necessary satellites of gastritis, any more than laryngitis or any other secondary affection that may or may not exist. Still, if you have gastro-enteritis to deal with in the winter time, you may be for the most part certain that they will be accompanied by bronchitis or by pectoral congestions in varied degrees, actual peripneumonies in some, simple congestions in others.

Further than all this, the skin fails not to take part in the irritation; the most compressed parts of it become red; a kind of erythema, that may proceed to phlegmonous erysipelas, takes place. Certain annual constitutions exhibit these erythematic and

erysipelatous affections in a prominent manner. They sometimes appear to alleviate or cure, at other times to aggravate the primary disease.

Phlegmons around the articulations, at the margin of the anus, &c. are observed to arise; but this is not always the case, and is dependent on the predisposition of individuals, the age, temperament, previous habits, &c. In infancy, you see congestions about the head; in adult age, in the winter season, and in persons with a plethoric constitution, the same take place in the lungs; in those who have employed an improper regimen, they occur in the digestive canal, in the liver; in those too assiduously given to study, or who suffer from grief, who are of the melancholic temperament and pusillanimous, the irritation predominates in the brain, and induces an afflux of blood thither; in those who have an irritated skin, or have had darts, it fixes on the skin, especially during the spring time; in the winter there is a concentration within the digestive canal and the lungs; in the spring and summer, there is greater facility towards congestions in the encephalon; in the autumn, there is a disposition to the predominance of irritation in the great intestine; in puerperal patients, there is tendency to inflammation of the uterine region, &c.

This is a vastly extensive subject, and requires further development; but for the present the above rapid description may suffice.

—o—

INTRODUCTORY LECTURE

TO A

COURSE ON THE THEORY AND PRACTICE OF MEDICINE.

DELIVERED BY DR. UWINS,

At the Free Hospital, Greville Street, Hatton Garden.

Winter Session, 1835-6.

LECTURE I.

THE objects of that science on which I am this day to discourse in an introductory manner, are manifestly those of counteracting or preventing the physical and moral evils to which man, in civilized society especially, is constantly obnoxious.

Respecting our power thus to dislodge evil and substitute good, much difference of opinion has always obtained. By some encomiasts, we are exalted almost to the eminence of the divine nature, while others have not only *en badinage* ridiculed our pretensions, but have argumentatively maintained, there is an absurdity in the very supposition that medicinal aid can be made to meet, with any avail, the wants and woes of our species.

The truth in this, as in most other matters, which are not capable of being brought into

the compass of the exact sciences, lies probably about mid-way between the extremes of implicit faith and sturdy scepticism. The sober judgment of mankind will be generally ready to allow a validity to, and repose a confidence in the claims of the therapeutic art, which even its opponents are not seldom the readiest to have recourse to, when disease attacks or death threatens.

Wholesale and unmodified objectors to medicine seem influenced by the radical error of forgetting the artificial state of man. "As he immerses from his primeval simplicity," says an eloquent writer (Dr. Lambe), "do the furies of disease rush upon him, and would scourge him back into the paths of nature and simplicity." But into these confines he will not, he *cannot* again enter. The die is cast, and the choice is only left him of applying the counteractives of art, to the derangements produced by art. And oh! what a glorious sight is opened up before us in reference to this particular. What would London be, with its thousands of streets, and almost millions of inhabitants, were it not for medical science, medical polity, and vastly improved medical practice?

Pestilence is stripped and crippled to such an extent that it retains not a tithe of its former malignity and power. It sits like Buuyan's Pope and Pagan, grinning impotence. The ravages of small-pox and all its dire sequelæ, thanks to Sydenham and to Jenner, are now comparatively matters of history, rather than of present fact.

Rickets and other deformities; notwithstanding our effeminate habits, are rapidly departing from our land. In order to witness the horrors of ague and all its dreadful accompaniments, we must now transplant ourselves to the shores of the Mississippi. Fevers are washed, or diluted, or drank away, under the demands of nature, or are dispersed in air—thin air—instead of being, as they were wont to be, blanketed, and fostered, and fed, by nosological nonsense, or theories which it is painful, because it is humiliating, to think of. Nurseries! why, they are absolutely new localities; and nurses, thank science and good sense for it, are almost a gone-by race. Common-place notions, and sapient apothegms, with their dire and cruel tyranny are going down to "the vault of all the Capulets." Real knowledge has begun to assert its claim and put forth its powers, and the practical consequence is, and evermore will be, freedom, and health, and happiness.

Only contemplate the ruddy cheeks and happy countenances of those children you daily see in your walks about the wide and open streets in the outlets of the metropolis, and look at the health and cleanliness and hilarity of their attendant nurses; (I speak now, of course, merely as a physiologist, and philosopher and political economist); look, I say, at the blooming countenances of the children and their young nurses, and you will

be compelled to the confession, whatever your sentiments may be respecting the Cockney school of poetry and of literature, that the Cockney school of beauty and health is at the very least its equal.

This is no *Deus intersit* flourish : I speak forth the words of truth and soberness. Here is art countervailing art, with ample and unanswerable witness ; and had we of the faculty no other triumphs to display than those just adduced, medicine would even then possess sufficient to boast of on the score of the past, and plenty of promise in reference to what is to come. But the absolute and immediate success of practical medicine is in other ways constantly demonstrated. If I give opium to relieve pain, and the desired effect follows the administration of the drug, I not only thus effect a temporary good, but in many cases operate a lasting or radical benefit ; for the pain which I have thus subdued at its onset, would in numerous cases have otherwise set up an irritation in the frame, which irritation might have proved a source of permanent, and at length have proceeded to organic mischief.

It is curious enough that some individuals who question the powers of medicine, speak with approbation of surgery ; but surely I have been as rationally and as usefully engaged in curbing the rage of any form of disease, which even in its etymology implies pain, as he has been who shall have reduced a dislocated joint, or relieved a strangulated hernia ; and I have been, if it may be allowed me to say so, more philosophically employed, inasmuch as anatomical knowledge and mechanical tact are sufficient for the surgeon's purpose, while to detect disease through all its tortuous workings through the fibres and fabric of the body, demands much more than handiwork dexterity or structural knowledge.

Whether the two departments of the art may be exercised with the best effect by one and the same individual is another question ; and it is one which would be out of place to discuss here with any thing like the amplitude which its importance demands. I may only just remark, that to some extent the physician and the surgeon will ever be the same, on account of their provinces being so intermixed, as to defy such separation as is practicable in other sciences and arts ; yet still it must be admitted that surgery in its higher departments demands so minute and so continued a recognition and recollection of every ramification of every vessel and every fibre almost of the animated machine, and at the same time calls for that manual dexterity which may exist to the exclusion of more reflective habits, and greater capacity for philosophical deduction, that it seems in the nature of things the amalgamation proposed by some, can never go beyond close alliance—that a good physician will be a good physician still, and an able surgeon, an

able surgeon still, to the end of the chapter. One thing, however, is certain amidst all the discordance of sentiment ; and it is to you, gentlemen, as important as it is certain, that the studies of the surgeon and those of the physician, during the days of pupillage at least, are not separable ; *all* the departments of the healing or restorative art claim the student's attention ; and having acquired his preliminary knowledge he will go out into the world, armed at all points, and ready to practise any branch to which inclination may urge, or accident direct. I will employ the very short hour before us, by first presenting you with an exceedingly slight outline of the progress of medical doctrine ; by, secondly, offering you my opinion on the attempts that have been made to arrange and designate disordered states ; and finally, in giving you a sketch of the plan I mean to pursue in the present course.

Medicine was in the earliest days surgery, and surgery was medicine. We do not hear much in ancient times beyond extracting darts and applying medicaments to wounded surfaces ; and even when internal maladies became the subjects of recognition, poets, priests, and philosophers were the charmers away of pain, and the restorers of healthy action ; nor can this be wondered at when we take into account the amazing power which imagination possesses in actually changing physical conditions. Even in our days of controlling, calculation, and scientific certainty, the lame have been made to walk at the mandate of persons supposed to possess potency equal to the required effect ; and who is there ignorant of the fact that precisely the same medicine will operate with diversified influence, according to the strength or weakness of the patient's faith in the prescriber's competence ?

On this topic I shall have again to observe, and to amplify in that part of the course which will be devoted to what are usually called nervous diseases ; and I now hasten to my proposed history—or rather historical sketch of the progress of our art from the period when it came to be cultivated and practised distinctively and exclusively.

Hippocrates was the first fully to accomplish this separation. He has therefore been styled the father and founder of physic. This great man was born in the Greek island Cos, and he lived about four hundred years prior, as did Galen about one hundred years after the birth of Christ. His fame was principally founded upon his habit of minutely investigating the circumstances and exciting sources of disease ; but his deductions as to internal localities were not seldom exceedingly vague, in consequence of the little that was known of the structure and functions of the parts. The success of his practice, however, was proof of what a great deal may be effected by a minute observation of symptoms directed by judgment, even though the

pathological source of such symptoms be not understood.

Very soon after the time of Hippocrates, anatomy came to be more extensively cultivated, but some of the earliest investigators of structure were too frequently obliged to limit their investigations to the brute creation.

Now it was, as related by Celsus, that divisions were instituted in medicine, and at this time two sects sprang up, under the denomination of Empirics and Dogmatists; one disclaiming all appeals excepting to experience—the other contending that facts were useless without philosophy: thus, as is still too much the case, engaging in disputations which resolved themselves into mere logomachies—the talkers about experience not seeming to be aware that “to think is to theorize,” and that the *merest observation implies a process of thought*; while the Dogmatists called that philosophizing, which amounted to little more than dressing up thought in a cumbrous and unmeaning phraseology. The celebrated John Hunter reasoned as did the Dogmatists of old, when he talked about “the life of the blood,” and of this fluid coagulating from “the stimulus of necessity,” which is no more than saying, “the blood coagulates because it must coagulate.”

The atoms of Epicurus were also at this time made subsidiary to medical theory; and molecules, and pores, and masses, and movements, were introduced into its doctrines. Then the methodic creed put forth its pretensions—the disciples of which proposed to exempt themselves both from the occult reasoning of the Dogmatists, and the mere observation of the Empirics. It was in this school that indications of treatment founded on the analogy of maladies were broached.

When Galen first taught medicine, he proposed the restoration of Hippocratic simplicity; but with this simplicity he conspicuously interlarded his own theories; he had, however, the advantage of writing when anatomy and its attendant physiology were in a somewhat advanced state; and an attentive reader of his works will find scattered through them many indications of some physiological doctrines, which in a measure deprive some modern suggestions of their claim to novelty; and there is a good deal of phraseology still in vogue which originated in Galenic Philosophy. (*Nerves of Sensation and Motion.*)

Galen's authority continued paramount until the downfall of the Roman Empire. The overthrow of this gigantic power buried European philosophy under its ruins, and monks and mysticism came now to be the order of the day.

But science, like commerce, is so restless and enterprising, that, dam it up in one part, you will soon see it break out in another. Learning, expelled by superstition from Europe, soon found its way into more Eastern nations;

and Arabia strove to imitate the fame of Rome and Greece. To the Arabians we are indebted for many valuable additions to the *Materia Medica*, but the advantage which was gained to medicine, as a whole, from these cultivators of the science, was perhaps the introduction of clearer notions than had hitherto been maintained, on the difference between epidemic and contagious distempers; on which subject, much however of obscurity to this day prevails, partly, as I shall have occasion hereafter to shew, on account of the very little that is known of atmospheric changes, as regulating and modifying disordered action.

As to the theory and practice of medicine, the Arabians did little more than copy, and badly translate the Greek and Latin authors.

The mention of a singular controversy that occurred during the prevalence of Eastern science, may serve to indicate the complexion of these times. Hippocrates had directed that blood should be drawn in pleurisy, from the arm nearest the part affected. Some of the Arabian physicians contended that it ought to be extracted from the opposite side; and this controverted point was discussed with so much ardour, that an edict was issued from the University of Salamanca, forbidding every one to pursue the Hippocratic injunction. The members of the University even endeavoured to obtain an edict from Charles V. to confirm their authority, alleging that the practice they opposed was no less pernicious to medicine, than Luther's heresy had been to religion!

To the Crusaders and the Saracenic invaders of Spain, are we indebted for the re-introduction of learning into Europe; but from the decay of learning to the commencement of the 16th century, nothing occurred in the way of improvement, sufficiently important here to be mentioned.

At the close of the 15th century Paracelsus was born. He was a native of Switzerland, and soon became conspicuous as a bold innovator, ridiculing all that had gone before him, and making of medicine a sort of alchemic art. His converts were many, but the most learned and respectable physicians of the time continued to abide by the doctrines of Galen.

It was in the year 1628, that Dr. William Harvey, a native of Britain, first announced the important discovery of the blood's circulation; a discovery which furnished a new framework for the whole compass of medical institutes. The announcement, however, was not at first well received. Most of Dr. H.'s contemporaries refused to subscribe to the truth of the doctrine, while others were busily engaged in proving that the discovery itself had been anticipated*.

* It is delightful for the patriotic Briton to reflect, that this has ever been the land of “master minds.” Who does not know, and exult in the consciousness, that our Newton

To Servetus, among others, was the credit awarded of having actually made the discovery, while Harvey, it was maintained, merely methodised and amplified the facts, so as to give them the appearance of novelty.

But the fact itself soon came to be misused and misapplied. As the disciples of Paracelsus had derided the ancients and resolved every thing into a kind of chemistry, so the chemical now in its turn gave way to the mathematical mania, which by axioms, postulates and corollaries, attempted to explain the functions of life, and the features of disease.

Afterwards a species of metaphysics usurped the chair of medical learning. Dr. Stahl, first suggested the idea of a rational soul, to whose directions and decisions the medical practitioners should listen and bow. Hence the *Viris Medicatricibus Naturæ*, which still, in their ghostly forms hover over the speculations of medical writers. Indeed this is but a round-about way of expressing a familiar fact, viz. that there is in nature a tendency to resist and regulate the inroads of malady.

Boerhaave attempted to recal the faculty to ancient authorities, and by combining in a measure Hippocratic Principles with the chemistry of the day, he proposed a system of his own, which principally turned upon the notion of mechanical and chemical changes in the circulating fluids, and this (vague as it was), introduced what has been named the humoral pathology; a pathology which Dr. Cullen tells us he found prevalent, when he was appointed principal professor in the Edinburgh University.

Dr. Cullen however, himself, reverted rather to Hoffman's views, which by a sort of antithesis to the humoral doctrines, particularly looked to the vital solid as the *primum mobile* of morbid being. Hence he (Dr. Cullen) borrowed his notions of spasm, a state to which I shall afterwards have occasion to refer; and with this spasm he got the Stahlian doctrine of *Vis Naturæ* interwoven, so as to constitute a system, partly from Gaubius and Hoffman, and partly from Stahl. Now then, action and reaction, spasm, and resolution of spasm, by the agency of the *Vires Naturæ*, subverted the previous notions of humours and obstructions, which were handed over to the *profanum vulgus* of the time.

gave laws to the material—our Bacon to the mental world? What Englishman can fail to contemplate without delight, that his is the country of Shakspeare and Milton? Harvey, we have just heard, gave to all vital essence a base to stand on. Black was the first to unlock the prison-house which held aerial substance in bondage, and it was his grand conception which let out latent heat from its numerous indwellings, and gave ample range and scope for the rich employment, and magnificent application of all its mighty energies.

Brown, indeed, ridiculed the spasm of Hoffman and Cullen, and proposed in its stead, the vague and inapplicable doctrine of excitability—vague, inasmuch as the change effected under the name of excitement, has never been satisfactorily defined; and inapplicable, because Brown's principles of excitability are contradictory, and one remedy in different doses ought, in his system, to supersede the employment of all others.

It is evident that Brown himself was conscious of having discovered the polar star by which future practitioners were to steer their course through all the intricacies of practice. He informs us, in the masterly preface to his *Elementa Medicinæ*, that during the twenty years he had given his mind to medical matters, he was, for the first five, occupied with receiving what he imagined instruction from others. The second lustrum found him principally engaged in teaching this false or imaginary knowledge to others; he thirdly began to entertain doubts whether he were not in a wrong course, for all, upon investigation, appeared *sine dulcissima rerum, luce veri*. And it was not until the last five years, that truth began to dawn upon his mind. “Solo quarto lustro, veluti viatori, ignota regione, perditis viæ vestigiis, in umbra noctis erranti, perobscura quædam, quasi prima diurna lux demum adfulsit.”

Darwin, in his *Zoonomia*, a work which at one time was too highly appreciated, and now is too sweepingly disregarded, mixed Brown's excitement with simple and compound laws regulating the fibrous and sentient system, and thus constituted a theoretical edifice, so as to include the several varieties of morbid being, as disorders of irritation—sensation—volition—and association.

So far as I have given my attention to the Hahnemann system of medicine, it appears to me founded on the reverse doctrine of what has hitherto obtained. Instead of *contraria in contrariis* it is *similia in similibus*, which, according to our German systematic, ought to direct the practice of the therapeutist. But, what analogy can be found between paralysis and minute doses of vegetable and mineral poisons, I have yet to learn. I should, indeed, place the whole affair on the same shelf with astrology, animal magnetism, and other mystic stuff to which our ingenious neighbours the Germans are so partial—did I not know that the principal apostle of the new faith in this country (Dr. Quin), is both a scientific and an honourable man—and did I not recollect that phrenological dicta appear to me in a much more favourable light than they did when I first heard them announced.

Such, generally, is an outline of medical systems, which it will be seen are more or less strongly marked by three radical errors. In the first place, it is assumed that vital and deranged action are traceable to one governing or master principle. Secondly, the several framers of successive hypotheses, con-

found efficient with final causation; and in the third place, natural philosophy, or the science of inorganic existence, is forced into an *unnatural* union with medical or rather with vital philosophy. So that during the whole time that theorizers have been reasoning, their exertions have proved no otherwise availing than the incidental discovery, and in some measure false registry of isolated facts; but even this last has been of service: for while the registry has often been defective and fallacious, it has sometimes proved correct and efficient; for example, even from the wildest and most unwarrantable of Brown's assumptions, legitimate inferences and practical principles have been beneficially adduced. (Sthenia and Asthenia).

"To think," it has been well remarked, "is to theorize." And those who oppose empiricism to theory, are, as before intimated, warring about words. We are obliged either by a process of our own mind, or by following the dictates of others, to register observations according to their inferred analogy; so that it is rather a question of hypothesis and theory, or of true and false generalization, than a question between facts and theories, which ought, nay *must* regulate all our sentiments and opinions on matters that are not susceptible of mathematic proof. An individual who talks about an ounce of fact being worth a pound of theory, talks absurdly—because practice, to be of any value at all, necessarily stretches itself out beyond the isolation of single circumstance. If I relieve pain, and afterwards wish to accomplish the same purpose, I am not aware without inquiry—that is, without referring to my mental register, or my written record—whether pain in the second demands or will admit the same treatment as pain in the first instance; so much for the opposition that has been set up of fact against inference.

Even during the present day, assumption of an eclectic spirit, in contradistinction to the hypotheses and futilities of by-gone times—that tendency to illegitimate generalization to which I have above referred—is sufficiently conspicuous among medical writings.

In some respects, indeed, we find false *registry* to be more especially mischievous among our contemporaries than it was with our predecessors; the head, the liver, the heart, the blood-vessels, the stomach, the nerves, and the membranes, have been looked up to, by successive theorists, as the main-spring of disordered action; even when such disorder owes no locality, but is at it were diffused through all organic space; and practitioners have been led wide of their mark by these topical assumptions; while pathologists have been employed in phraseology, which is any thing but correct.

I state this without desiring to undervalue the decided improvements which have recently done honour to the age, and credit to our

science. My only wish is to check the tendency there is, at all times, and in all things, to satisfy ourselves that we have got to the furthest point, when we have only made some little way in the correct path of procedure; to repress a disposition still lingering among us to *verba magistri* authority; and to lead your minds into the habitual consciousness that medicine is not a science which will always bear the adaptation of demonstrable—leading principles; that analogies even, often fail us; that every successive case is as it were a new study; and that while we assiduously apply ourselves to the cultivation of those branches of science which embrace medicine in their therapeutic application, and which themselves admit of their several and separate degrees of demonstrable or physical evidence—that while we learn anatomy, and physiology, and chemistry, and botany, and even surgery and pathology, upon principle—we must be contented in actual and practical medicine with scientific observation; and he, after all, will be the most successful physician who, in the language of phrenology; shall be possessed of, and exercise the largest share of the perceptive faculties, joined with a capacious causality, in order to lead him to correct inferences from materials which lie before his mental grasp, often in the most puzzling and almost contradictory seeming. He must take up the whole of the broken machinery, and put the parts together with promptitude and skill; promptitude, because delay is often highly dangerous; and skill, because he must not be looking into the liver, or scanning membranous lesion, or talking vaguely about digestive organs merely, while the whole bearings of the deranged condition at once summon his comprehensive regard.

But I must pass on briefly to notice nomenclature and nosological classification—subjects which have occupied much the thoughts, and employed largely the pens of medical speculators.

Now, it will at once occur to you, that the very attempt to identify a *disease* by certain parts and properties, as the botanist names a plant by its generic and specific characters, must be, in some measure, a vain attempt. "More than half the cases," says Wilson Philip, "we meet with, are *combinations* of diseases, rather than simple diseases." He ought to have said ALL are such; for of so complicated a nature is the human frame, that it is impossible disorder should have existence in one portion of it, without extending itself to others. For example, pulmonary affections are named and classified from symptoms. We talk of consumption, of bronchitis, of asthma, of pleurisy, of hydrothorax, of hydrops pulmonum, and so forth, but none of the affections, which are the leaders or characterizers of these several maladies, ever exist alone; nor are any one of them, or all of them together, the same in shewing upon different individuals.

When, therefore, a systematic names a disease, the enunciation must be considered as in some measure presumptive and uncertain, unless, indeed, by a sort of *metonymical* management, we substitute the *cause* of the disease for the disease itself—as when we say of an individual that he has a *cold*; but, even in this case, how great is the confusion and indecision that are induced! If a person talk of having a cold in his head, in his chest, in his limbs, he employs any thing but precise language; for it is the property of cold, or more properly speaking, of change in temperature, to produce what we should call spasm at one time, and in one locality, and in one individual; while in other times, and places, and persons, it occasions various kinds and measures of inflammation, congestion, hæmorrhage, fevers, &c.

But besides this source of error, another objection of a formidable nature applies itself against this metonymy—or in other words, this principle of denominating a malady from its supposed source, since a great diversity of sentiment still exists as to the nature and operation of several of the causes themselves. In the minds, for example, of many, the word typhus gives rise to the idea of a specific or peculiar poison acting as a contagion; while many others conceive that cold, famine, filth, and other deranging powers, are occasionally equal to its production.

In imagining, then, distinctive marks of diseased states, as referrible to particular or peculiar sources, we shall find ourselves embarrassed by every successive step, seeing that an identical cause may engender a diversity of effect, or a variety of symptoms, and finding, moreover, that the causes themselves are sometimes enveloped in such obscurity as to be variously discerned by various speculatists.

Then, from name to classification. How conspicuously do we find in this last the principle of analogy to fail us! Hæmorrhage, in Cullen's Nosology, is arranged in the same division with intermittent fever. And wherefore? Is it because the two morbid circumstances possess any character in common, as do the number and form of petals in plants of the same species? No—it is simply because they implicate the blood-vessels, while other maladies are nervous, and others depend more especially upon faulty excretions.

“Why not, it may be said, take any one part or organ, and, recognizing its deranged conditions, class them as appertaining to the organ affected, thus forming a topographical nosology?” The very complication above hinted at, would prevent accuracy, did we attempt it in this mode; and further than this, the locality of morbid states, did we always ascertain it, is very often but the second or third link in the chain, while the original and primary sources are to be found in the sentient system. Thus we may call hydrocephalus and epilepsy disorders of

the brain, but then we separate them from other maladies, as dropsy in the one case, and hysteria in the other; the one a lymphatic, the other a nervous derangement, with which they have more, so to say, fundamental or primary alliance than with any morbid states of the brain itself.

In a word, the animal system, especially the human frame, is so thoroughly a wheel within a wheel—so absolutely dependent upon its well or ill doing by the excitations without, and circumstances within, so diversified in its original texture, and so susceptible of modification from its exposure to a multitude of irritating causes, that when deviation from healthy standards occur, they do so with such marked irregularity, as not only to defy accuracy in classification, but to prove that the very principle itself, of nosological division and detail, is fallacious and ideal; and yet we must have some guide in our course of observation, especially when we attempt the task of teaching medicine to others.

On this account I shall select that chart by which we are to steer our course through our future meetings, which, although necessarily and in the very nature of things fallacious, yet, which in my mind, to say the very least, is as little objectionable as any that has come under my inspection; this scheme has, too, the advantage of falling in, more than all others, with the order that is generally observed both in medical tuition and medical examination: I mean the system of Cullen, which recognizes the three leading principles of animate being; namely, the *circulatory* or moving power; the *sentient* or percipient power; and the *absorbent* or repairing power: circulation more or less complicated, assimilation more or less separate, and sensation more or less distinct, being those distinguishing faculties which divide organized from lifeless matter.

Cullen adopts the term *Pyrexia* when treating of those deviations from health which engage especially the blood-vessels. Under the term *Neuroses* he ranges maladies of perception, sensation, and intellect; and by *Cachexia*, his third leading division, he indicates those disorders which have particular connexion with the secretory and absorbent system. As, however, from the causes just hinted at, we find ourselves assailed at every point when we come to individualize or locate maladies by this or any other scale, it would appear to me to be more instructive first to go over in a general way these natural divisions, and the affections peculiar to the above-mentioned functions, and then, bearing in recollection these land-marks, as it were, set to work more topographically; beginning by affections of the head, and proceeding downwards through the viscera.

But, as we find some disordered states which refuse to be located even with these qualifications, we must, in reference to these, proceed upon another principle, and endeavor

vour to designate the derangement by the peculiar something which seems to have engendered it. In this division we shall have to include contagions and fevers, and other anomalous or cryptogamic complaints : these we must treat of as their sources appear more or less evident ; and the consideration of these sources will lead us into the question of contagion and infection, about which much of discordant sentiment still prevails. Many of the eruptive fevers which differ from other skin maladies, will here fall before us for consideration ; but on these disputed points, while I endeavour to be clear and intelligible, I shall at the same time study to be as brief as shall consist with clearness.

In the above remarks, the order of the course to be pursued has been pointed out. I have only to add that a brief anatomy and physiology of each part will be attempted, prior to treating of its disordered conditions ; this, however, will only so far be pursued, as to render more familiar the local pathology of the organs, and thus make it more impressive : minute anatomy, and systematic pathology, you will, of course, be taught in other places ; but all the items which go together to form the sum total of medical science, are likewise so blended that their complete separation by respective teachers is neither practicable nor desirable.

At our next meeting we shall be engaged in some preliminary remarks on disordered action and therapeutic agency ; and having concluded these, we then proceed to consider the laws and circumstances of the blood's circulation, with its prominent and leading derangements. From the circulation we pass on to the assimilating function, and then conclude this portion of the course by taking a survey of the nervous system, both in its healthy and deranged habitudes.

At this part of the course, Gentlemen, I propose to make a pause, and occupy one or more meetings by inquiries as to the quantum and kind of knowledge I may find among the pupils in reference to general function and disordered being. And this plan I purpose to adopt through the detail of disease ; thus having extended our investigation over the whole of pulmonary affections, I will, with your permission, put questions relative to the anatomy, functions, and pathological circumstances of the heart, the lungs, and all the membranous structure that is found in the thoracic cavity ; the same course will then be pursued in reference to the viscera and membranes, and vessels of the abdominal cavity : we afterwards go on to the extra-abdominal viscera and their connexions, and ascertain how the pupil stands as it respects his knowledge of kidney, and vesical, and uterine, and other connected ailments. And among the cryptogamia and anomalous derangements, fevers, contagions, rheumatic affections, and some others, will be inquired into, according to the order that

shall have been pursued in the course of the readings and remarks.

Thus will the teacher and the taught be rather disposed to a reflective than a routine manner of conducting inquiry, and engaging in disquisition ; and thus will the pupil be made more ready to meet those investigations which will be elsewhere entered into, respecting the degree of his attention as measured by the amount of his acquirements.

LECTURES ON THE PHYSICAL EDUCATION AND DIS- EASES OF INFANTS, FROM BIRTH TO PUBERTY.

BY DR. RYAN.

Delivered at the Medical School, Westminster

Dispensary, Gerrard Street, Soho :

Session 1834-35.

LECTURE I.

—

Vices of Conformation and Diseases of the Urinary Apparatus.

Diseases of the Urinary Apparatus.—This apparatus comprises the kidneys, subrenal capsules, ureters, bladder, urachus, and urethra. Every one of these parts has been found diseased during intra-uterine life. A few examples may be quoted.

The urinary and genital apparatus, developed at an early period in the foetus, necessarily offer a numerous series of anomalies : on this account a multitude of imperfections have been observed in the different parts which compose them ; such as the augmentation and diminution of the natural size of the kidneys, their division into several lobes, their re-union, adherence, augmentation of the calibre of the ureters, their absence, the communication of the bladder with the navel at the middle of the urachus. Fleischmann relates a case in which there were no traces of the urinary apparatus, although the intestinal canal and other abdominal organs were in their natural state, &c. All these anomalies, as well as the different malformations of the genital organs which constitute the numerous species of hermaphroditism, relating directly to the divers monstrosities, either by excess or defect, are entirely foreign to the subject we are at present treating.

The ureter has been obliterated, and the kidney distended, by incysted dropsy in an infant of four days old (Billard). The kidneys may be absent, or there may be only one, and this situated on the vertebrae (Meckel). The lobes may be separated, and sometimes the situation of the kidneys is changed : they have been found higher or lower than usual, and adherent to surrounding organs. Sometimes the walls of the

bladder are found much thicker than in their natural state; at other times the internal surface of it is red, and contains pus or purulent mucosity, and is consequently affected with true inflammation. M. Moreau related a case before the Académie de Médecine in 1828. A woman, pregnant for the fourth time, was confined, three weeks before the end of utero-gestation, of a small delicate girl, but whose abdomen was very large, being distended by a liquid. At the rupture of the membranes, and more especially after the expulsion of the infant, there was a great quantity of water discharged; M. Moreau estimated it at eight pints. The infant died thirty hours after birth, and, on opening the body, he found almost two pints of yellow-reddish serosity in the peritoneum, the intestine contracted, being not more than the size of a common lumbricus, and without the least signs of meconium; the bladder was distended so as to reach as far up as the navel, its walls being thick, hard, studded with red points and fleshy columns, as well-marked as in some bladders of the adult; the ureters distended to the size of the finger; in fine, the kidneys were very voluminous, and resembling two large tumours.

The renal capsules, which are very much developed in the fœtus, and whose functions are at present entirely unknown, have as yet presented no defect of formation consisting in an anormal or incomplete development, or in varieties in number, form, situation, &c.; as to their morbid alterations, we possess but one case, observed by M. Andral, who, in making an autopsic examination on a phthisical female, who died at the sixth month of utero-gestation, found one of the renal capsules inflamed, and in a state of suppuration.

Distention and displacement of the bladder are sometimes observed in the fœtus (Chaussier, Duncan, and others). The anterior wall of the bladder has been absent; there was at the same time a division of the abdominal wall and a separation of the pubes, so that the internal surface of the posterior wall presented external to the abdomen. Dr. Duncan considered this deformity more common to male infants (Edinburgh Med. and Surg. Journ.); but it has also existed in female. Meckel found bifurcation of the bladder and the formation of several sacs (S. A. Ehrlich, *Chirurgische Beobachtungen*, t. 2).

The bladder of the fœtus may not only be affected with inflammation, but, as in the adult, it may also contain calculi of a greater or less size. F. Hoffmann has observed a remarkable example (*Opera Omnia*, t. vi). The lady of a German prince had experienced, during pregnancy, severe pains, occasioned by the pressure of a calculus situated in the kidneys. She was, nevertheless, happily delivered of a daughter, which, a short time after its birth, appeared to ex-

perience violent pain during the evacuation of urine, and which died towards the third week: on examination, a calculus of the size of a peach-stone was found in the bladder. M. Denis has also met with, in an infant that died a few days after birth, from intestinal affection, numerous calculi of a moderate size in the bladder. It will not be said that these calculi were formed during the short interval between the birth of the infant and its death; and it should be remembered that the development of these bodies indicated an epoch anterior to that of birth; what appears more extraordinary is, that, in the fœtus, the bladder always contains a greater or less quantity of urine. The urethra may be obliterated, or considerably contracted, in any part of its course. Its orifice has been impervious, and in such cases it opens anterior or posterior to the scrotum (hypospadias), or on the dorsum penis (epispadias), or on the side of the organ (pleurospadias). When the urethra is impervious at the orifice, the bladder will become distended, and an incision necessary. When there is an opening on the inferior, superior, or lateral surface of the penis, there is no necessity for operation, as the urine may be as freely evacuated as in the normal state of the urethra.

Hydrocele.—Another disease with which the fœtus is often affected, is hydrocele. This always takes place from the non-obliteration of the inguinal ring, after the passage of the testicles. The serosity, which forms the tumour, secreted itself by the peritoneum, which it lubricates, passes from the abdominal cavity through the ring which is left open, and of which it prevents the obliteration, and forms in the scrotum an oblong tumour, more or less bulky and transparent, which increases in volume when the infant is in the vertical position, which diminishes, on the contrary, and even entirely disappears when it lies or when it is pressed, which causes the great distinction between this species of hydrocele and that met with in adults. These tumours, on account of the enormous volume they acquire in certain circumstances, may oppose the completion of parturition. An example of this is to be found in one of the Edinburgh Essays: the tumour was so large that the fœtus could not traverse the pelvis, and labour could not be effected till the volume of the tumour had been diminished by the discharge of a portion of the fluid it contained. A possibility of a return of this secretion into the abdomen should be guarded against by the application of a proper bandage in closing the aperture which gave passage to the liquid: a method of treatment always successful when hydrocele is not complicated with other diseases.

The kidneys have been inflamed during intra-uterine life; but it is difficult to detect the disease in new-born infants, on account of the great vascularity of the organs under

consideration. Dissection has shown ecchymoses of the kidneys of the fœtus in utero. They have also been marked with yellow lines, when the fœtus was jaundiced.

In some intra-uterine infants the kidneys have been so softened, that they yielded to the pressure of the finger, and were lacerated with facility.

It also appears that calculous nephritis, or gravel in the kidneys has occurred during the same period of life. M. Denis has detected gravel in the kidneys, ureters, and bladder, in new-born infants. M. Billard attests the same pathology, but never saw well marked calculi, though he does not consider their formation impossible.

The internal surface of the bladder is generally of a white satin colour, but it is sometimes dotted with petechiæ, and highly vascular. In infants after birth, the kidneys and bladder are sometimes inflamed, though the disease is of very rare occurrence at this period of life. Underwood states that the symptoms of nephritis are extremely obscure, and may evade detection during life, and arise from ischuria renalis. Retention or suppression of urine has been observed in young infants; and after death the bladder was found empty. In such cases there was no secretion of urine, that is to say, the kidneys did not perform their function. The morbid appearances alone established the cause of death.

The bladder is occasionally inflamed in very young infants, as at the age of fifteen days, two months, and four months, the internal membrane was excessively red and tumefied. There was suppression of urine and distention of the bladder in one of these cases, and intense inflammation was found at the neck of the organ.

In some cases cystitis is caused by improper diet, intestinal inflammation, dentition, and sometimes by acute and chronic disease of the brain, or spinal marrow, or of both. In such cerebro-spinal affections, there is also paralysis of the bladder.

New-born infants suffer from *retention of urine* for a day, when the urethra is imperious; and this generally attracts attention. It also happens that an infant may not pass urine for a day or two, independently of cystitis or impervious urethra. In such cases the warm bath, warm fomentations, or the application of a bladder half filled with warm water, are the best remedies. A few drops of nitrous ether may be given in barley water or milk. These means usually afford relief when there is no malformation or inflammation of the urinary organs. If they fail, catheterism ought to be employed if the bladder is distended. When there is reason to suspect cystitis, which is a very rare disease, a leech or two may be applied to the hypogastrium or perineum, the bleeding encouraged by warm fomentations, and afterwards a warm bath will be highly useful.

According to Morton and other writers,

infants have been affected with diabetes mellitus, and cured by a milk diet, with a weak chalybeate water.

Catarrh of the bladder rarely occurs in infants at the breast, but is more frequent to those of a more advanced age. It may be caused by worms, tenesmus, dentition, or stone in the bladder. It requires the same treatment as cystitis. In slight cases the urine becomes white on cooling, and somewhat resembles milk. This condition is usually attributed to worms, but really depends on irritation or slight inflammation of the bladder. It is generally relieved by mucilaginous drinks, with proper doses of the sedative preparations of opium. The diet ought to consist of the vegetable jellies, such as arrow-root, sago, tapioca, &c.; and if the infant's strength is much reduced, of animal jellies, chicken-broth, beef-tea, &c.

Gravel and urinary calculi are also diseases of infants. If the infant is at the breast, the nurse ought to be advised to take vegetable, and avoid animal food. When the calculus is composed of lithic acid, which may be suspected when the sand passed in the urine is of a red colour, the best remedies are lime water, soda water, soda in table beer or barley water, calcined magnesia, or a combination of these in appropriate doses, according to the age of the patient.

When the sand is white, we may suspect the phosphates, and exhibit dilute nitric or muriatic acid, or muriated tincture of iron. I have repeatedly observed the good effects of the last remedy combined with opium in my hospital practice, in infants from one to five years of age. In these cases, however, as in those of adults, all medicinal remedies often fail, and lithotomy is the only resource. It is worthy of mention, that infants are liable to calculus in the kidney and ureter, as well as in the bladder, and also in the urethra. Examples of the last are by no means rare in dispensary practice.

The existence of calculus may be suspected when the infant cries or suffers from tenesmus on attempting to pass urine, when the fluid escapes drop by drop, appears reddish, or tinged with blood, or deposits a glary or puriform sediment. The infant also conveys its hand to the genital organs. The pain has been so great, that convulsions supervened, and death followed. The disease continues to the age of two or three years, defies all remedies except lithotomy, and which has often been performed with complete success. When calcareous matter impacts the urethra, it may often be removed with a probe; and if it cannot be dislodged, the urethra should be opened behind it when practicable.

Incontinence of Urine in Infants.—This disease is very common to infants, and often continues until puberty, and it is said that girls are more liable to it than boys. The causes of this disease are insensibility, re-

laxation, or paralysis of the bladder. There are different degrees of insensibility; some infants do not suffer from incontinence but during sleep, and others when awake; and when the bladder is too relaxed to retain the urine, the patient is languid, fretful, or irritable; the digestion is variable or bad, the countenance is pale, there is a black or bluish circle round the eyes, and general emaciation follows.

According as age advances, the disease disappears without any medicine, and especially at puberty; but in other instances, the disease ceases from the fifth to the tenth year, and returns at the twelfth or fourteenth, which is the period of puberty, on account of the excess of irritability of the genital organs at this epoch of life. Sound sleep is a cause of this disease, as the patient may not perceive the impression of the urine on the bladder. It is on this account that children who are fatigued from exercise, and sleep profoundly, often wet the bed.

The means for curing incontinence of urine must vary according to the causes which produce it. Thus, if it depends on general atony of the system, tonics and chalybeates are indicated, with cold bathing, or affusion of cold water on the genital organs. I have found a few drops of laudanum or the sedative solution given at bedtime, an effectual remedy in infants, and children arrived at puberty. Several cases of girls at the age of puberty, affected with this inconvenient disease, were successfully treated by me, with opium, at St. John's Hospital, the Free Hospital, and Western Dispensary. The effect of this remedy on the brain causes an unusual state of innervation during sleep, and breaks through the anormal state of the cerebro-spinal system, which causes the disease. It is scarcely necessary to observe, that due attention should be paid to the general health. Children should be prevented from, or cautioned against, irritating the genitals with the hand.

—o—

Reviews.

First Report of the Commissioners under the Poor Law Act, addressed to the Right Honourable Lord John Russell, His Majesty's Principal Secretary of State for the Home Department.

IN obedience to the Poor Law Act, the Commissioners under it are required to make an annual Report to the Secretary of State for the Home Department. Their first Report is now before us, and shews the degree of improvement in the condition of the poor, the diminution of bastardy, and the abuses of the medical profession.

It appears by several returns from different parts of the country, that the diminution of bastard children is from ten to one; and in a certain district in the county of Flint, that "of the number of women who applied to be married, fourteen in fifteen were pregnant; but in the eighteen marriages which we have had since last August, all the ladies except one retained their virgin shape, and appeared without their mantle."

The Commissioners admit many imperfections in the act, and among these the want of proper judicial functionaries, who ought to be accessible to the poorest of the community, to decide upon the injury of seduction, without compelling the poor to resort to the superior courts of law, which are too costly.

We now come to the medical department, on which we find the following remarks.

"Amongst the evils we found ourselves called upon to remedy, were a large class connected with the administration of medical relief. In our present Report we deem it necessary only to advert to some of the chief evils of this class, and to the measures we have adopted with relation to them.

"We found it a practice, in the great majority of instances, for a medical man to contract with the parish for the supply to the settled paupers of the parish with medical attendance for a small fixed sum, on the expressed or implied condition that he should be allowed to make whatever charges he pleased for his attendance and treatment of non-parishioners, under suspended orders of removal, or an order of medical relief by the overseer. When the patient has recovered, he is sent home to a parish with a bill for medical attendance including charges for medicines at the highest rates. Against these charges the distant parish to which the pauper belonged had no adequate protection. The pauper was exposed to the danger of being supplied with medicines considerably beyond what was required for his proper treatment. Instances have come to our knowledge where, in large populous parishes, the profits of attendance upon paupers under such circumstances, has been upwards of 300*l.* per annum. The inferior officers have been fed by the medical officers to search out and give him information of the cases of this description. As a further evil of this system, we may mention that paupers with their families have been removed from their parishes at a great expense, when each head of a family would otherwise have preferred remaining and seeking employment in the parish where his sickness occurred. By countenancing these

practices parishes were in the habit of creating burdens for each other. As a check to this system, and to the general expense of medical relief, we have generally required that medical services should be retained by contract and open tender, including as a condition, that the medical officers should attend at the same charge all patients on the order of the overseer, whether the patients were parishioners or non-parishioners."

The small fixed sum, or rather beggarly pittance allowed parish surgeons, may have occasionally led to the *abuse* complained of; but the worthy commissioners do not suggest adequate remuneration. They advertise for the lowest bidders, and obtain young and inexperienced officers. They seem to consider disease among the poor unworthy of the best treatment.

"In regulating the appointments of medical officers within the new unions, we have acted on the presumption that by the words of the Act (that the medical officer shall be 'a person duly licensed to practise as a medical man'), it was intended to include equally physicians, surgeons or apothecaries duly licensed to practise as such. Applications have been made to us to prescribe, as the qualification of the medical officer of any union, that he should be a member of the College of Surgeons as well as of the Apothecaries' Company; but as at present informed, we do not think that the public interests would be advanced by confining the qualification within narrower limits than those traced by the words of the Act, and which conform to the general practice. With respect to the general professional qualifications of the medical men who come within the words of the Act, we have relied on the diplomas of those who are charged by the Legislature with the duty of examining the qualifications of the candidates for practice, being assured that the recent improvements in medical practice and education are such as in general to render the later diplomas certificates of a degree of competency, equivalent to much practice on the parts of those who have had an earlier education. Under these circumstances we have considered that the interests of the public and of the profession itself were the best served by keeping the situations of medical officers in the new unions open to the competition of the whole body of medical practitioners. Instead of attempting to fix the price of the services of the medical practitioners for the union, we deemed it the most advantageous that each practitioner should fix the price of his own services, under competition. Amongst the inducements to accept these appointments, are the credit of the appointment of medical officer to an union by a Board of Guardians, the wider fields these appointments offer for the display of care

and skill, and for obtaining reputation leading to more profitable practice; inducements differing in degree, but similar in kind to those upon which men of the most eminent skill find it to their interest to give their services to the chief medical institutions of the country. We may be sure that the medical practitioner will, in fixing upon his terms, do nothing which he considers will not on the whole be advantageous to himself; and next, that he will consider the interests and advantage of his own profession. We have found it necessary, as a security against undue charges even under competition, to adopt as a rule that the aggregate charges for medical relief within the new unions shall not exceed the aggregate of the former expenditure for medical relief in the separate parishes now included in the unions. Instances have occurred where the local medical practitioners have combined to prevent a competition. The course taken in these instances for the protection of the rate-payers, and to secure the best treatment to the paupers, has been to suspend our sanction to the appointments, and to cause advertisements to be made to throw open the office to the competition of practitioners from a distance, or of the profession at large."

The profession alone are to blame for the competition scheme, for had they demanded remuneration for their services in hospitals, dispensaries, and other public institutions, it could not have happened. It is preposterous to continue gratuitous attendance, when every parish must find medical aid for the poor.

"In some unions, as in the Wycombe union, it has been provided that the terms of the contract should be a remuneration, at a given sum per head, on the number who receive medical relief; but with the proviso, that the gross charge should not exceed a given amount. It is stated to us in evidence, that this mode of proceeding, though adopted reluctantly by the medical profession, has operated very beneficially. The surgeon of the Amersham union states, in the course of an examination, 'I approve of the system; but the amount in the present contract is inadequate; I think I shall lose a guinea a week by it. In some of the parishes it is at present only one-third of what I have received in former years for the same time. But I approve of the system, for these reasons: it is a self-acting check upon the relieving officer in giving improper orders, or withholding proper orders; upon the applicant for medical relief, in making him feel that in receiving it he is a pauper, and causing the parish a specific charge for him; and upon the medical man, by causing an inquiry into each case, so that none can escape attention; and by that means, also

secures proper attendance to the patient. Indeed, the mode of contract forms a complete system of check and security in cases of pauper medical relief, the want of which was so much felt under the old system.'

"Has it tended to curtail the evil of sending all parties to the parish doctor for medical relief, which was so prevalent under the cases of contract in gross?"—"Yes, it has; I have many cases now that I am attending as independent patients, who used always before to come to me as paupers. One case is that of a woman of Penn; her son is a master bricklayer, with whom she resides, the cottage and garden their own. She has a daughter about thirty, a sempstress, who gets a very good living. This woman was, with her daughter, always attended by the parish. On my telling this woman that the parish paid a specific sum for her, she refused to be attended, and now pays for herself. There are many cases which evidence this effect of the system.'

"Of course, the new independent patients pay you?"—"Yes, they do; they pay us at the time they have the medicine.'

"Now, although you do not receive so much from the parish contract, will not the amount by these new independent patients more than make up the difference?"—"No, I think not; but it will go towards it.'

"We anticipate that the introduction of a better system will be beneficial for the destitute sick, as well as beneficial to the labouring classes generally; and that it will be found conducive to all proper interests of the respectable portion of the medical profession.

"It will, however, be observed, that the change in the system has not, in many instances, been so long in operation as to develop the whole of the effects which may be anticipated from it, in promoting voluntary and independent associations, to provide for the casualties of sickness and mortality.

"But even now the reports made to us of the very satisfactory effects of the operation of the rule, are becoming daily apparent. We cite the following passage from a recent Report made to us by our Assistant-Commissioner, Mr. Hall, as illustrative of the tenor of other incidental communications on the subject:—"The good effects of your arrangements as respects medical relief, are showing themselves in the shape of medical clubs among the labourers. One of the surgeons of the Wallingford union told me that several were in process of formation in his district; and I have heard that elsewhere the labouring class has evinced the same degree of foresight and providence; has given the same proof that, when thrown upon his own resources, and taught to rely upon his own exertions, the independent labourer can and will adopt measures answering to the necessity of the case.'

"Mr. Gulson states, in a recent Report

from Oxfordshire, 'Medical clubs are starting up in all directions. The proceedings of the board, as regards the medical department, have already been productive of the best results. Highly respectable medical men are undertaking to attend all cases for an annual subscription of 2s. for a single person; and for 4s. 4d. they engage to attend a whole family, however large, so that it does not include children above 16 years of age. At Witney, Benson, and other places, the labourers are subscribing in considerable numbers to independent medical clubs.'

"Mr. Gilbert reports to us, that in several parts of Buckinghamshire similar effects resulting directly from the change of medical relief, have been developed in a striking manner."

The establishment of medical clubs among the labouring classes, very forcibly demonstrates the want of confidence in the medical officers of parishes and unions, whose remuneration is wholly inadequate for the proper supply of medicines and medical aid. Every medical practitioner knows well, that he cannot afford medicines and advice to a family for a year for 4s. 4d.; and such an agreement is most unjust to those who make it. Let the Poor Law Commissioners consult the Medical Corporations, and they will find that our opinion is correct.

—o—

A Statistical Inquiry into the present state of the Medical Charities in Ireland, with Suggestions for a Medical Poor Law, by which they may be rendered much more extensively efficient. By Denis Phelan, Surgeon to the County Tipperary Gaol, and to the House of Industry and Lunatic Asylum, Clonmel, &c. 8vo. pp. 324. Dublin: Hodges and Smith. London: Longman and Co. 1835.

THE author of this work is entitled to the greatest praise for the immense labour, trouble, and expense which he incurred, as a provincial surgeon, in collecting the scattered materials which he has accumulated. As an individual, he encountered many difficulties in obtaining replies from the medical officers of the hospitals, infirmaries, dispensaries, lunatic asylums, and other public charities in Ireland, as some of those whom he addressed were interested in the abuses of such institutions. The majority, however, afforded him every information, and with a promptness which re-

flects great credit on them. He also addressed his circular to some of the provincial physicians and surgeons of England, from whom he received satisfactory answers. He also obtained a vast deal of information from the evidence given before the Irish Poor Law Commissioners, and from that given before the Parliamentary Committee on Medical Education and Practice; and he now publishes all the result of his inquiries in the work before us. He shows in the most glaring light the abuses in all the public charities in the sister kingdom, and suggests very satisfactory means for their correction. The object of the author is twofold; 1, to prove the inefficiency of all public charities as regards the poor, and the easiest means of rendering them valuable; and 2, to improve the better remuneration of the medical profession, and to adopt a just reform in appointing them to such institutions. It will appear by the sequel that the author has been most successful. He is, in our opinion, entitled for his benevolent exertions, to the esteem of every friend to science and suffering humanity. He informs us, in his preface, that he has been connected with hospitals, infirmaries, dispensaries, &c., and was recommended by Viscount Duncannon and Lord Lismore to Lord Heatherton (late Mr. Littleton), as assistant to, and one of the medical inspectors of, the Irish Poor Inquiry, but for some unknown reasons, he suspects on account of being a medical reformer, he was passed by. This we think was extremely probable, in consequence of the pestiferous influence of the Dublin medical corporations, than which there are not more filthy sinks of corruption in this or any other country. Fattened and fattening on monopoly, the misnamed heads of the profession in Dublin were, like our own immaculate heads, to be consulted by the Royal Commissioners; and their advice as to the selection of a medical reformer as an inspector of abuses in hospitals, dispensaries, &c., may be readily imagined. Our author was undismayed by this result, and prosecuted his useful labours. He might have exclaimed with the ancient warrior, "*veni, vidi, vici.*" He has defeated the Dublin monopolists by the publication of a work which refutes the chief of their one-sided

and partial evidence delivered before Mr. Warburton's Medical Committee. He concludes his preface in language which will prove "gall and worm-wood" to Irish medical corporators, and poison them like other vile and perishable insects.

"A work of this nature can only be desirable to those members of the legislature who feel an interest in the improvement of such institutions as are considered likely to be useful to the sick poor, to the medical profession, and to such governors of hospitals, dispensaries, &c., as are anxious to improve their respective institutions. If it answer the purpose, even though but imperfectly, of turning the attention of these respectable classes to a subject as yet but indifferently understood, I shall consider my time and labour to be amply repaid."

There cannot be a shadow of doubt that the present House of Commons will be greatly influenced by the self-evident and incontrovertible pile of evidence presented in this volume; and none more than Mr. Warburton, Mr. Wakley, the Attorney-General for Ireland, and other zealous friends of medical reform. The medical profession at the other side of the Irish channel owe a debt of gratitude to Mr. Phelan; while the governors of hospitals, infirmaries, dispensaries, and all public charities to which medical officers are appointed, cannot fail to be convinced of the defective state of these institutions.

We now arrive at the commencement of this most important work, and place the heads of its contents before our readers.

Mr. Phelan commences his introduction by giving an account of the "probable number of medical charities in Ireland, with their income, expenditure, &c." He then shows "the necessity for, and advantages arising from, charitable institutions to all classes;" and next adduces proofs "that infirmaries, fever hospitals, and dispensaries, are quite insufficient to meet the wants of the sick poor." Ample experience, from connexion with these institutions, has long since convinced us of the truth of this statement. We shall however allow the author to prove it beyond all doubt. His observations are so interesting and instructive to all medical practitioners, that we quote them fully, and they abound with the most valuable statistical information relating both to England and Ireland. We think this work

so valuable, that we shall review it at great length, though we hope to condense our extracts into less than fifty-six pages, or the space allowed by some of our contemporaries to productions of much less merit. We are anxious to inform our readers, both foreign and domestic, of the state of the public charities of Ireland, as regards the medical profession, and give them information which is now published for the first time.

It will appear by the perusal of the following facts, that it is impossible to separate them, and consequently we place them before our readers.

“There are no public documents to enable us to ascertain the exact number, or the entire expenditure, of the medical charities of Ireland, though in no country could such be furnished with equal facility, as the greater part of these institutions receive public aid in one shape or other. In the reports of the ‘Commissioners for auditing Public Accounts in Ireland,’ and published by order of the House of Commons, we have a short account of the Dublin hospitals, and of all the county infirmaries; and a return made by the different district lunatic asylums, and printed by the same authority, gives a very satisfactory view of these charities. The parliamentary report of 1832, though very defective, still gives much information as to the number, expense, &c. of fever hospitals. There never has been any report on dispensaries, which appears extraordinary, as considerable sums are expended on them, nearly one-half of which is raised by county presentments, affording a correct record, which there would be little trouble and no great expense in publishing. I have myself taken considerable pains to ascertain the number of medical charities in this country, the expenditure of each, the number of patients attended, &c., but though I have got a good deal of information on the subject, I have not yet had returns from all. The following is, therefore, given, not as an accurate account, but one which, I think, will be found nearly so:

Dublin hospitals (exclusive of several lying-in hospitals and ophthalmic institutions lately established)	7
County and other provincial infirmaries	38
Fever hospitals, including three in Dublin	64
Dispensaries	528
District lunatic asylums, including the Cork asylum	11
Total	648

“The following will give a tolerably accurate view of the annual expenditure of these charities:

Dublin hospitals	£28,701
Provincial hospitals, or infirmaries, as they are usually called	26,426
Provincial fever hospitals	13,607
Dispensaries	60,000
District lunatic asylums	22,965

Total annual expenditure £151,699

“To the above we may add 10,000*l.*, which is probably under the sum expended on the medical business of workhouses, and the lunatic asylums connected with them, making, in all, for public medical charities, an expenditure of about 161,699*l.* per year, and in which I do not include the funds raised for a considerable number of medical institutions *entirely* supported by subscriptions, amongst which are a few fever hospitals, several dispensaries, and a considerable number of lying-in and ophthalmic institutions, the entire expense of which cannot be under 14,000*l.* a year.

“The sources from whence this expenditure is supplied, are:—

Treasury grants to county infirmaries, and Limerick fever hospital, deducting pells and poundage	£ 2,653
Annual parliamentary grants to Dublin hospitals	14,374
County presentments for public charities	82,839
Subscriptions and donations for the above 648 charities	39,078
Petit sessions and other fines	1,742
Produce of property belonging to several of the hospitals	23,225

Total £163,911

“All these items, except those for fever hospitals and dispensaries, must be correct, as they are taken from official documents. The exceptions are estimated thus: the above alluded to parliamentary report gives an account of forty-six provincial fever hospitals, which, on an average of the years 1829, 1830, and 1831, cost 9,993*l.* 10*s.* 4*d.* per annum, exclusive of the expenditure of the Dublin fever hospitals. There are, at least, fifteen more that have not been included in the report of 1832, which I know to be on as extensive a scale as those that are. The entire annual expense of these sixty-one provincial hospitals would, therefore, be about 13,607, and the annual presentments for them about 9,000*l.* I am in possession of returns respecting the dispensaries of twenty-one counties, which I think are pretty accurate: they contain 340, and the annual presentments for them is 18,625*l.* 14*s.* 5*d.* With the exception of Mayo, I believe the remaining eleven counties contain dispensaries in as great proportion, and present for them at about the same rate. In that case the entire number must be about 518, and the yearly presentments 28,900*l.* Those of the cities of Dub-

lin, Cork, Waterford, Limerick, Kilkenny, and Galway, are not here included, and are about ten more, making for all Ireland 528 dispensaries; the presentments about 30,000*l*. This sum, doubled, will give the annual expense, as the grand juries cannot present more, though they may, and often do, less than the amount of subscriptions and donations.

"The amount of petit sessions fines, marked above, is that paid into the treasurers of county infirmaries; but this sum must fall considerably short of that yearly received at these courts, much of these fines being, I know, handed over to other charities, though illegally.

"It is impossible at present to ascertain the exact amount of subscriptions and donations annually paid to all these charities, but when the official accounts are published, I think it will be nearly 50,000*l*. a year.

"From this brief account of the numbers and the yearly expense of the mere medical charities of this country, or rather of those chiefly for whose support public aid is granted, their great importance will be at once seen; were they viewed merely in a financial sense, the sum annually raised off the public, both directly and indirectly, for their support, probably not less than 150,000 a year, would be a fair subject for the consideration of the political economist. But these institutions must be looked on very differently by every enlightened and humane individual, who wishes the improvement of Ireland, and has any knowledge of the condition of its people. When it is recollected, that, even during the most plentiful seasons, a great portion of the population of this country is in want of the common necessities of life—that contagious fevers constantly exist more or less in every county and in every town in the kingdom, but which, whilst food is only moderately cheap, seldom affect any very considerable number—that the condition, and I am sorry to be obliged to add, the habits of many are such as, on the occurrence of famine and distress, to greatly favour the origin and the rapid extension of that or of any other contagious disease amongst the poor, from whom it is sure to be communicated to the more comfortable classes, a circumstance well known to have frequently taken place within the last forty years—the great value of so many medical institutions for the relief of the sick poor, and to check the progress of contagious diseases, must at once be admitted. In the following pages I shall give several instances of the utility of fever hospitals and dispensaries in preventing, in checking, and in curing fever. And when the condition of the poor is considered, and it is known that in these institutions we have such valuable resources, without which, in fact, a deficient potato crop, or a scarcity of food in any way produced, must be sure to renew those frightful epidemic fevers which

we have already so often experienced, it will be seen that these charities are essentially and indispensably necessary for Ireland. Some instances will, and many more might be given, of places in which fever raged for years, sweeping away numbers of the poor and not a few of the rich, where the establishment of well regulated fever hospitals, or even of well managed dispensaries, gave such a check to its ravages, that contagious or malignant fevers but very rarely now occur. And though in such districts famine and distress have again and again recurred, and the same causes still exist to favour the origin or extension of this Irish plague, the means placed at the disposal of the governors and medical officers of these institutions have been productive of the most gratifying results. In such localities, as far as the sphere of the hospital or dispensary extends, fever, it will be seen, has become much more rare amongst the poor, the rich are but seldom attacked; and, where many valuable lives had been annually lost before the establishment of a fever hospital and dispensary, that disease is not only lessened in frequency, but, what is still more remarkable and gratifying, it is of a far milder character.

"When we find numerous facts of this kind clearly and indisputably established by the reports of persons having daily opportunities of witnessing them, and on whose evidence no suspicion can rest, and at the same time know, that, in many towns and districts, similarly circumstanced in respect to the comforts and habits of the population, but in which no fever hospital or well managed dispensary has been in operation, fever has been much more frequent, more virulent and fatal, we surely cannot, or at least ought not, be blind to the great advantages which both poor and rich derive from well regulated medical charities; nor to the numerous miseries which are suffered by the poor where no such institutions have been established, or in districts too remote to enable them to derive any adequate benefit from those which are perhaps within some miles of them.

"There is, I believe, no country, with a moderately dense population, in which we shall not find that a great number are unable to provide themselves with *efficient* medical aid when seriously ill. Even in wealthy England, a vast number of the working classes apply to the hospitals and dispensaries for advice and medicines. Dr. Walker, of Huddersfield, a very high authority, has ascertained that "little less than 70,000 objects are annually relieved at the London hospitals," independent of the still greater number receiving medical aid from the twenty dispensaries of that great and wealthy city. In the commercial and wealthy town of Liverpool, he informs us that in one year (1826), no less than 32,000 patients had been admitted to the three

dispensaries of that place, of whom 9604 were visited at their residences; and that in one year, little less than 36,000 objects received relief from the medical charities of that town. On examining the Rev. Mr. Oxendon's valuable 'Statistical Report of the principal provincial Hospitals in England,' I find that, not alone in such commercial and manufacturing places as Bristol, Leeds, Manchester, Birmingham, Sheffield (whose five hospitals alone give medical aid to 40,796 patients yearly, independent of a probably still greater number attended by the dispensaries), and the like, a great proportion of the population receive gratuitous medical aid, but that in the districts which, according to Marshall's Parliamentary Digest, are purely agricultural, great numbers of the working classes are relieved by these charities; and this, it should be recollected, independent of those attended by the parish medical officers. When we find this to be the case in England, where the tradesmen, and the manufacturing and agricultural labourers are so much more comfortable and better paid than in Ireland, we may be certain, that, with equal facilities to obtain medical advice from hospitals and dispensaries, a still greater number would here be found to apply for it. And accordingly we find this to be the case. From returns with which I have been supplied, through the kindness of the medical officers of the different charities in Dublin, and from other documents, it appears that the number of patients recommended in one year to five dispensaries in that city, viz. the Dublin General Dispensary, Talbot, Meath-street, George's, and South Eastern, is not less than 55,705; and that the medical attendants of the Mendicity Institution had charge of 9887; that at the Baggot-street, Mercer's, new Meath, and Jervis-street hospitals, and the Coombe Lying-in Hospital, 167,772 prescriptions were dispensed to *externs* during the same period; that at the Institution for the Diseases of Children, and at two others, for diseases of the skin, 12,000 were attended; and that thirteen hospitals received 15,566 *intern* patients, of whom 5700 were fever cases. If we calculate that each *extern* patient attends four times, which is considered by many a fair average, then the number of patients relieved at the above five hospitals is no less than 41,943 annually, making a total of 135,091 individuals receiving gratuitous medical assistance in the city of Dublin in one year (1833), when neither fever, nor any other disease, was particularly prevalent. I shall hereafter show how small a portion of the hospital *interns* come from beyond the precincts of that city, and, lest it be supposed that the surrounding country furnishes any considerable number of the *externs*, it may not be amiss to observe, that, for a population of less than 120,000 of the county of Dublin there are twenty-one dispensaries. In the

city of Cork, the north and south infirmaries and the fever hospital treated 1603 *interns*, and 21,179 *externs* in one year, and the dispensary 12,062, of whom 2947 were repeatedly visited at their own residences; in all 34,844. In Clonmel the Fever Hospital *interns* and the *extern* recommendations, on an average of five years, were 5771 annually, about three-fourths of whom were residents of the town and suburbs. The following table will more clearly show the proportion of sick poor relieved by the medical charities of three places in each kingdom:

Place.	Population.	No. of Sick in one Year.
London . . .	1,500,000	270,000
Liverpool . . .	200,000	36,000
Manchester . . .	227,000	18,951
Dublin City . . .	265,000	135,091
Cork City . . .	115,000	31,844
Clonmel . . .	17,000	4,329

Place.	Proportion of Sick to the whole population.
London . . .	1 to $5\frac{1}{2}$
Liverpool . . .	1 to $5\frac{1}{2}$
Manchester . . .	1 to 12
Dublin City . . .	1 to 2
Cork City . . .	1 to $3\frac{1}{2}$
Clonmel . . .	1 to $3\frac{7}{8}$

I have here assumed that each of the London dispensaries gives medical aid to 10,000 persons yearly, which, in a city of such resources and population, is only a moderate number.

"From these and numerous similar facts, which could be given, it is evident that both in England and in Ireland a considerable portion of the people of each country find it necessary to apply for professional assistance to the medical charities; but that the proportion in this kingdom is greater from well-known causes, viz. poverty and bad habits inducing disease, and rendering tradesmen, small farmers, and labourers, when overtaken by any serious illness, unable to pay for advice or medicines. As, therefore, in wealthy England we know that so great a proportion of the population do actually apply for advice to the medical charities, and, as might be expected from the condition and habits of the Irish, a still greater here, it may be fairly assumed, from these and other circumstances which have been alluded to, that, in this country, these institutions are indispensably necessary, and that without them there would be no safety for the health or lives of either rich or poor. The medical charities are in fact the *poor law* of Ireland, always, when well managed, and as far as their sphere of action and the extent of their funds admit, conferring vast benefits on the sick poor, chiefly by means of the professional assistance they administer. They are also, though in a much less limited way than could be wished, the *medium* of supplying the same class with

food and drink, sometimes with clothes, fuel, or bedding. And they often enable the wealthy and the middle classes to obtain professional assistance more satisfactorily, and at less expense, by locating well educated practitioners in country districts, where, but for such institutions, there would not be sufficient inducement for them to settle.

"It is therefore clear that the medical charities of Ireland are productive of great advantages to all classes of its inhabitants; that the benefits they confer are not confined alone to the sick poor, but extend very widely, and embrace even those who are able to pay for professional advice. It becomes then a subject of no small importance to enquire whether these institutions are numerous enough, possess sufficient funds, and are so managed as to be capable of affording adequate professional aid to the sick poor of Ireland. This, it is well known, they are not; for though in particular places, the most efficient relief is given to the sick poor of every class within a certain district, I shall have to give proofs, which I believe cannot be controverted, that numerous as our medical charities are, and large as the sums appear which are annually expended in their support, a vast portion of the sick poor of this country neither do, nor can obtain relief by their means; and, as there are no other substitutes for them, that great suffering, the loss of numerous lives annually, and other serious injuries are the consequences. When treating of each class of these institutions I shall show how far they are defective and inadequate to meet the wants of those for whom chiefly they were intended. At present I shall only give the following facts in proof of the insufficiency of our infirmaries, fever hospitals, and dispensaries."

Here we pause for the present, but shall next week give the author's contrast between number, extent, &c., of English and Irish infirmaries, fever hospitals, and dispensaries. We have adduced sufficient evidence to prove the philanthropy, benevolence, laborious research, and indefatigable industry of the author. Legislators, philosophers, the medical profession, the present generation and posterity, will do him justice, and award him unqualified praise, and the highest esteem for his great exertions to better the condition of his poor fellow-countrymen, and of the profession of which he is a real ornament.

(To be continued).

Observations on the Principal Medical Institutions and Practice of France, Italy, and Germany; with Notices of the Universities and Cases from Hospital Practice; to which is added an Appendix on Animal Magnetism and Homœopathy. By Edwin Lee. London: Churchill. pp. 216.

MR. LEE states in his Preface, that his volume will "be considered by those best qualified to judge, as presenting an impartial, and not inaccurate sketch, of the medical and surgical practice in France and Italy." We do not profess ourselves qualified, by experience, to judge of these qualities of his work, as regards the last named country; and we are happy to vouch for them as regards the former. But to qualified or unqualified judges, we venture to say the book will be pleasing. None are so capable of happy condensation of what they say as English writers, and none so capable of appreciating and so desirous to find that condensation as English readers; in reading, as in travelling, they care not for the scene on either side the road, but have their thoughts and hopes fixed on the end and aim of their prelections and peregrinations alone. Happy in this power, Mr. Lee has produced a small work that to the student desirous of information on the state of the continental schools and practice, will be of the highest value, combining, as it does, so much of the *utile* with the *dulce*—so many facts with so concise a manner of announcing them.

The first part of this volume is occupied with a review of the French Medical Institutions. Speaking of the facilities of dissection in Paris, the author remarks, that "they have some disadvantage, in the inducement they offer to the students to hurry through their dissection in a careless manner"—which is very possible: but it is by no means a sequitur that "the greater neatness of dissection observed in the English schools is no doubt to be attributed to the comparative scarcity of bodies." Were this the case, it would be better to have a course of dissections resembling the Barnicide's feast, an imaginary body before us, which we might anatomize even to the nicety of Haller's ultimate muscular fibre. No; something must be allowed for the time the French student has for the pursuit of his

anatomical knowledge—the course of study required being four years, and not twenty months—and much to the temperament of the youthful Frenchman: at all events, let us not, for the sake of “careful dissection,” relapse into the “plentiful scarcity” of subjects, that roused the murderous inventive faculties of the Burkes and Hares of past years!

We proceed briefly to enumerate the hospitals and infirmaries of the French capital.

The Salpêtrière contains six thousand individuals, the greater number of which are old and infirm females, the remainder being afflicted with mental alienation, epileptic and cancerous diseases, and the whole are divided into curable, incurable, and idiots. The first division is confided to M. Pariset, the second to M. Mitivié, and the third to M. Falret.

The Bicêtre contains three thousand persons, including the insane: the latter are attended by MM. Ferrus and Lelut.

The Maison Royal de Charenton is exclusively for the insane, and contains six hundred beds. M. Esquirol is the physician; in his statistics of the hospital from 1826 to 1833 inclusive, the causes of insanity were in the following proportion:—hereditary predisposition, three hundred and thirty-seven; domestic sorrows, two hundred and seventy-eight; reverse of fortune, forty-nine; political circumstances in 1830, thirteen; in 1831, fifteen; in 1832, three; in 1833 only one.

The Hospice de la Maternité contains four hundred and fifty beds: about three thousand five hundred accouchemens take place annually: no questions are asked on entry, and each patient may leave her child behind. A physician, two surgeons, and a midwife, perform the duties, assisted by one hundred and fifty female students of midwifery.

The Hospice des Enfants trouvés receives annually between five and six thousand infants: suckling infants are placed in one ward containing one hundred cradles. Three-fourths of the children received die, notwithstanding the favourable circumstances of locality and cleanliness.

The Hôtel Dieu contains twelve hundred beds, and averages nine hundred to nine hun-

dred and fifty patients constantly; there are only two hundred and twenty-four beds for surgical cases; three surgeons and ten physicians attend. The principal physicians are MM. Chomel, Piorry, Magendie, Recamier, and Trousseau, an abstract of whose particular modes of treatment is given. The present surgeons are MM. Roux, Sanson, and Breschet; every one knows that M. Roux's place was formerly occupied by Dupuytren. The practice of the latter able surgeon in some cases, as shortly described in the volume before us, we make no apology for extracting; they are the original views of a great and talented man.

“The nervous or traumatic delirium, which frequently supervenes on accidents and operations, and which, like delirium tremens, is marked by insomnia, continual restlessness, and absence of fever, was treated by M. Dupuytren by enemata of a small quantity of mucilaginous liquid, containing from six to twenty drops of laudanum, repeated three or four times, if the symptoms persisted, at intervals of six hours. This small quantity of laudanum, so administered, produces a more marked effect than three times as much taken by the mouth, and seldom fails to induce sleep, after the failure of other means. This kind of delirium leaves no traces of its existence after death: it most usually occurs in men of a nervous habit, and occasionally in women, but has not been observed in children.

“Wounds of arteries, if recent, are best treated by placing a ligature on the vessel between the wounded part and the heart. The only exception to this rule is when the artery is wounded near the extremity of a limb; in which case, in consequence of its free communication with inosculating branches, it is requisite to place a ligature both above and below the wounded part. A similar proceeding is required when the lesion of the vessel is of long standing, as the edges of the wound are then incapable of adhesion.

“Gonorrhœal ophthalmia mostly occurs from inoculation, but may supervene on the suppression of the urethral discharge, especially if the patient have been at the same time exposed to cold, or other exciting causes of ophthalmia. It should be treated by general and local depletion, revulsives, and emollient lotions. These measures are however insufficient, unless combined with the insufflation of a pinch of finely-levigated calomel, upon the ocular and palpebral conjunctiva, once or twice a day. One or two drops of laudanum should also be dropped between the eye-lids in the evening. The purulent ophthalmia of infants is essentially the same disease, and should be treated in a similar manner. Strumous ophthal-

mia was considered by M. Dupuytren to depend on inflammation of the retina, and was treated by the internal administration of belladonna, combined with other means indicated by the symptoms. From three to eight grains of the powder, or from one to three grains of the extract of belladonna, were divided into six doses: the patient took one of these every two hours; to prevent narcotism, either general or local, Seltzer water was usually administered at the same time.

"Gangrena senilis is not, as its name would imply, restricted to old persons. M. Dupuytren has termed the disease *Gangrène symptomatique*, believing it to depend upon inflammation and consequent obliteration of the arteries of the limb—ossification of the vessels, to which it was formerly ascribed, being only an accidental coincidence—the treatment consisted in venesection, repeated according to the urgency of the symptoms, low diet, cooling beverage, opium, and other sedatives, with emollient cataplasms to the affected part. By this treatment the average mortality is said to be as one to four. Previous to amputating a part affected with long standing disease, M. Dupuytren frequently established suppuration by means of blisters on some distant point. It was also his practice, after amputations, to wait an hour, sometimes longer, before dressing the stump: by this plan union by the first intention took place more readily, and the likelihood of hemorrhage was diminished.

"In prolapsus ani, M. Dupuytren excised two, three, or more folds of the skin on the margin of the anus, on either side. A similar operation was recommended by Mr. Hey. No dressing is required, and the recurrence of the disease is effectually prevented.

"Fissures at the margin of the anus may be divided into three kinds:—1st, those external to the sphincter, which are not very painful, and do not occasion spasmodic contraction; 2nd, those situated within the sphincter, affecting principally the mucous membrane—this kind causes tenesmus, and great pain, especially on the patient's going to stool; 3rd, those placed on the same level as the sphincter, are more serious and painful than the other kinds, which may generally be cured by simple dressings, emollient lotions, and sedative applications; whereas this variety requires the division of the sphincter on the fissure. M. Dupuytren was in the habit of prescribing an ointment composed of extract of belladonna and acetate of lead, of each a dram, to an ounce of lard, for alleviating the pain in these diseases.

"M. Dupuytren preferred excision to the ligature, for the removal of uterine polypi, in consequence of the greater facility with which the former is effected, and the few inconveniences it occasions when compared with the latter method. The patient being placed in the same position as for lithotomy, a speculum is introduced into the vagina, so

as to exhibit the tumour, which is then seized with a strong four-hooked tenaculum, with long handles (*pincés de museaux*), and gradually brought down through the inferior orifice of the vagina, the patient being recommended during the traction to strain as if in labour: on the division of the pedicle, the uterus immediately regains its usual situation. The operation is not in general very painful, and bleeding to any extent very rarely occurs."

La Charité contains four hundred and fifty beds. The laborious Velpeau is the first surgeon, and MM. Bouillaud and Rayer the physicians of the establishment. M. Bouillaud is a vehement partizan of the Broussaisian doctrines, and a most daring drawer of blood; thus, out of twenty-six cases of pleuro-pneumonia, each patient on an average was bled four times, cupped twice, and had twenty-four leeches applied: in about half the number of cases, blisters were also employed, and in one a purgative was given—successful practice, it would appear, for of the whole number, "two only died, twenty-three having been cured before the fourteenth day." M. Rayer is a "conforming" Broussaist.

La Pitié. The well known names of Louis and Andral are attached to the medical, and Lisfranc and Blandin to the surgical departments of this hospital. Mr. Lee lauds M. Lisfranc for his adoption of constitutional measures in surgical cases. It may be necessary to explain, that by constitutional measures, the author appears, throughout the book, to mean the employment of purgatives, and particularly of calomel—a rather narrow view of the matter, we may observe en passant. Lisfranc's clever operation of amputation of the cervix uteri is well described. The beds in the hospital amount to six hundred.

Saint Louis. Here are seven hundred beds, one hundred and eighty of which are for surgical cases, the remainder for cutaneous and scrofulous diseases. MM. Alibert and Bielt are the physicians in care of the majority of the skin diseases: the cases of psora are in a separate ward, under the care of M. Emery. Alibert uses chiefly external, and Bielt internal remedies, in the treatment of the complaints in question. M. Lugol has charge of the scrofulous patients: his practice is pretty extensively known in this country.

Hôpital des Vénériens contains six hun-

dred beds, and is too small for the number of patients. Three surgeons, MM. Cullerier, Ricord, and Manec are attached to the hospital. The former doubts the specific character of syphilitic affections, and acts very largely on his doubts, seldom employing mercury, and when he does, mostly in friction. M. Ricord is more free with its use, and generally gives the proto-ioduret. Gonorrhœa is treated much in the same manner as in England.

Hôpital des Enfants Malades. The acute cases here, are under the care of M. Baudeloque, and the scrofulous patients under that of M. Guersent. The latter order of patients, it appears, are placed in low ill-ventilated wards, little likely to ameliorate their condition. This is the more extraordinary, as M. Baudeloque in his late work, "*Sur la Maladie Scrophuleuse*," ascribes that disease to the want of pure atmospheric air alone. There is accommodation for five hundred, though only half the beds are usually occupied.

The Hôpital Necker, founded by the widow of the celebrated finance minister, is attended by MM. Bicheteau and Civiale. There are one hundred and twenty beds, which are chiefly occupied with cases of acute thoracic disease. We extract the following as a mode of treatment not generally known among us.

"Paralysis of the bladder, and vesical catarrh, in elderly people are treated in the following manner:—a stream of cold water flows from a reservoir fixed near the ceiling, through an elastic gum tube, having stop-cocks, and terminating in a silver catheter formed into a double tube by a central partition. The patient being in the recumbent position and the catheter introduced, the water passes into the bladder by one side and out by the other. A continued stream of water through the bladder is thus kept up for about ten minutes, and repeated every second or third day: the quantity of water passing into the bladder may be regulated by the stop-cock, so as to prevent undue distension. The beneficial effects of the method are attributed to the clearing away of the accumulated mucus, and to the tonic action of the cold water upon the bladder."

The Hôpital Cochin contains one hundred beds: it bears no particular reputation.

So much for the Parisian hospitals, which appear, from the account before us, to be conducted with a liberality of spirit that we

would wish to see imitated in those of London. Two prominent and well-turned features in the arrangements regarding them are, the admission of patients without other recommendation than that of disease, and the payment, for the most part, of the medical officers. If it be true, as Mr. Lee asserts, that the results of English practice are more successful than of Parisian treatment, it is equally true that English physicians and surgeons are much more chary of information to the students, of their valuable secret, than are the Parisian hospital attendants of their unsuccessful mode—the obvious reason of which is, that your London medical man, once in an hospital, cares not either for student or governor—the former *must* attend his clinique, and the latter *will not* pay him. Were the Parisian plan of visiting the hospitals as early as six in the morning obligatory *here*, we suspect it would be found mighty inconvenient and vulgar to be attached to them, and then all might stand a chance of receiving and giving improvement, and the precious privilege of withholding information would not be vested in a few, who bask in the smiles of those with whom rests the gift of that privilege. However, we are Jobs in long suffering, and await with patience the day-spring that shall enlighten our hospital wards—*arrive it must*.

In a chapter of "*Observations on Continental Practice*" (it should have been on "*French Practice*"), Mr. Lee gives a rapid sketch of the state of medical theories and practice among the Parisian faculty. Previous, however, to entering on this, he takes occasion to praise the system of concours, which he says "certainly affords the best guarantee to the public and to hospital patients, of the skill of their professional attendants:" at the same time he remarks, as regards its introduction here, that "under the present system, the voice of public opinion and criticism, far more strongly expressed in England than elsewhere, and the judicial investigation which ensues on fatal cases, where suspicions of improper treatment exist, are the principal securities for the capabilities of hospital professional attendants." Now, if Mr. Lee has no better reason than this for excluding the concours system from this country, he would have done well to say nothing about that system

at all: for when he asserts that "the voice of public opinion and criticism," and the "judicial investigation," secure capable men, he supposes that the fear of these things deters blockheads from seeking the offices in question; which is not found to be the case, as could be shewn in the persons of some few existent hospital attendants, from whom the voice of "public opinion" might in vain demand one idea, and whom "judicial investigation" would in vain attempt to shame.

The Broussaian doctrine, we are told, is on the wane in France: "the number of exclusive Broussaists is very small, although many of the profession still incline to the principles of that doctrine." At this we wonder not: Frenchmen are marvellously fond of changing theories, as well as dynasties; and when it is considered that in the last forty-five years, the nation at large has had nearly half the number of governments, constitutions, and governors, we may surely allow the medical faculty a little variety in their theories and despots. For us, we hold that the doctrines of Broussais are still destined to resume their sway, when each pathologist has gratified his vanity by styling himself the founder of a new system, and when that system has ran its brief career.

Mr. Lee finds great fault with the inactivity of French physicians, in prescribing medicines, and more especially purgatives: and the activity they do exhibit in depleting, he ascribes to the diffusion of the Broussaian doctrines. We agree with him, and consider the *veto* placed on the use of purgative medicines as by no means a strict deduction from those doctrines: the illustrious author of them certainly overlooked facts when he maintained their hurtful tendency in fever, even supposing that state to be a consequence of gastro-enteritis; this, however, is not the place to discuss the point.

Chronic diseases are mostly treated by hygienic means, mineral waters, &c.; and stimulant, tonic, and mercurial medicines abstained from. Baths form a very frequently applied remedy in France, whereas they are seldom thought of here. Auscultation and percussion, the author considers, give the French a vast advantage over most English practitioners. Why are not English medical students more frequently instructed in those arts?

The French surgeons the writer finds to be culpably negligent of general treatment in surgical cases; and he says they trust entirely to local applications: this is the fact; on the other hand, the French retort that we slay our thousands by over-dosing—which is also true. Healing of wounds by granulation is now pretty nearly done away with in theory, though Mr. Lee says it is maintained in practice. Arteries are now tied altogether à l'Anglaise; that is, without ligatures of reserve. The principles by which the treatment of fractures is directed are also very similar on the Continent and in England. Continental surgeons waste no long time in attempting the reduction of strangulated hernia, and they proceed to operate, and to operate cleverly too, for they always divide Gimbernat's ligament, which Mr. Lee considers to be the point of constriction, though Sir Astley Cooper does not. Lithotomy is performed by the lateral method, as in England, except that the bistouri caché supersedes the cutting gorget. The bilateral has however come into vogue; of seventy patients thus operated on by M. Dupuytren, six only died. In lithotrity, the method by perforation, as employed by M. Civiale, is now less generally adopted than that of breaking down the calculus by means of Jacobson's and Heurteloup's instruments. Flap operations are now less frequently performed in France than a few years ago. Amputations at the articulations are more frequent than in England. In burns and scalds stimulating medicines are less used on the continent than here. Urethral strictures are treated by rest in bed, a catheter being kept in the bladder, and its size gradually increased. Cold applications are not frequently used in France and Italy. Diseases of the eye are not so much attended to in France as in England and Germany, and the practice is in general inferior; there is no ophthalmic institution in Paris. The treatment of uterine disease is better and less empirical in France than England; and it would require to be so, for Mr. Lee tells us that "those diseases, as well as some others that supervene upon difficult parturition, are more prevalent" in the former than the latter country.

We shall take up the second and third parts of this volume next week; meantime we cordially recommend it to the profes-

sion, particularly to those about to take a professional gaze of the Continent.

**MEDICAL EDUCATION—NECESSITY OF
ATTENDANCE ON LECTURES.**

In our last number we alluded very briefly to the subject of medical education, on which we had not at that time leisure to dilate. Our contemporary the *Lancet*, in whose views we have generally found reason to acquiesce, has not, we think, treated this question with his wonted sagacity; we therefore propose to argue it freely, but without the smallest wish to interrupt the amicable relations which we have much pleasure in maintaining with a journal so influential in the good cause of medical reform: in saying this much, we are not apprehensive of the charge of obsequiousness—our alleged sins being usually quite of an opposite tendency.

Our contemporary testifies a horror of the “certificate system,” in which we entirely participate, in as far as it involves a monopoly on the part of certain schools; the whole doctrine of “recognition” is unto us an utter abomination: but when we are told that all medical lectures are useless, and ought to be done away with, and still more when it is proposed, as a substitute for the present system, that each surgeon should instruct his own apprentices in every branch of medical science—in other words that he should become a walking university—we cannot conceal our surprise that opinions so wild should proceed from the same source with those enlightened and liberal sentiments, to whose fearless announcement the profession mainly owes its approaching regeneration.

First, with respect to lectures.

It must be admitted, and has been admitted by us repeatedly, that *knowledge*, from whatsoever source derived, ought

to be the only thing required from the student at his examination; but the question is, can the requisite knowledge be attained under ordinary circumstances without attendance on lectures? Certainly not—unless by the course of private instruction proposed by our contemporary, which we shall presently show to be impracticable. Most branches of medicine, to be rendered even *intelligible* to the beginner, require the aid of demonstration or experiment; to say nothing of the greater strength and durability of the impressions derived from what we see than from what we hear.

“Segnius irritant animos demissa per aures,
Quam quæ sunt oculis subjecta fidelibus, et
Ipse sibi tradit spectator.”

And even with reference to those subjects whose illustration comes less under the cognizance of the external senses, the colloquial style of a lecture affords scope for much clearer and more minute explanation than can be expected from written treatises, to which the student, debarred from attendance on lectures, must chiefly resort for the exposition of principles, and for direction in his own observations.

These things being considered, we cannot perceive how a student is to be qualified for his profession independently of lectures, unless the affluence of his circumstances enables him to engage men of ability and experience as private tutors in each branch of medical science. But this leads us to the proposal of our contemporary, that every practitioner should, in effect, become private tutor to his apprentices.

We must confess that if this proposal came from any other quarter, we should be much disposed to laugh outright—but we *will not* laugh at the *Lancet*; with all its extravagances, and they are many, the *Lancet* has a right to the gratitude and respect of every medical practitioner in Great Britain.

Well then, by hypothesis, every general practitioner is to teach his

apprentices medicine in all its branches. *Exempli gratia.* An old gentleman who has practised for thirty or forty years in a country place, perhaps much to his own credit and the benefit of the neighbourhood, is to teach his apprentices *chemistry*. This worthy man has some floating notion that there be two such substances in nature as *hydrogen* and *oxygen*, and mayhap he may have an idea that an acid will turn syrup of violets red, and that an alkali will turn it green; and moreover, that there is a doctrine called “the doctrine of definite proportions,” which passeth the understanding of man; if all his apprentices do not turn out Davies or Wollastons, it is evident that they are very stupid lads.

Again. A very good practitioner, who began business many years prior to the publication of Paris and Fonblanque, is to instruct his young friends in medical jurisprudence. This honest man has once in his life been before a coroner, on which occasion his hair stood on end,

“cum sudor adimos
Manaret talos.”

Fodere and Orfila may shut up shop—our young gentlemen reduce state medicine to an exact science.

Once more. An apothecary resident at the Land's End, and rolling in riches of course, is to teach his youngers—what shall we say?—every thing. For this purpose he purchases a chemical apparatus which costs him rather more than twice his yearly income; he lays in a stock of subjects for anatomical purposes, and brings the county about his ears: he takes the young gentlemen out on a botanical excursion, and finds, on his return, that the greatest man in the neighbourhood has died of apoplexy, and, what is worse, the greatest woman has delivered herself of twins!—his occupation's o'er. Are not his apprentices ungrateful dogs if they do him not some credit after this?

But to be serious. Admitting what

is unquestionably true, that the professional acquirements of the general practitioner in the present day are frequently very extensive, does our contemporary really think that any one practitioner is competent to teach every branch of medical science? In all history we know of only one man equal to such a task; that man was Haller, whose versatility of talent, and variety of attainment, rendered him the wonder of his age. Let every country practitioner be a Haller, and we will admit his sufficiency to instruct his pupils in every department of their profession; let every day consist of forty-eight hours instead of twenty-four, and we will allow that he might find time to do so: but, as matters actually stand, we cannot but regard the pantosophical surgeon-apothecaries of our contemporary, as

“likest hovering dreams,
The fickle pensioners of Morpheus' train.”

We do not believe that lectures can be dispensed with, nor do we see any reason why they should; but we see much reason why the present infamous system of monopoly should be forthwith abolished. Let any regular member of the profession, who desires it, have a fair opportunity of distinguishing himself as a lecturer if he can; only let him not lecture on every thing—that would be as bad as the pantosophical apothecaries.

We quite agree with our contemporary, that the greater part of the lectures now delivered in the metropolis are most woful stuff; this is, because they are the products of recognized stupidity: let the field be thrown open to unrecognized talent, and we shall have lectures worth hearing.

Although we contend for the great utility of lectures as a part of medical education, and see no reason whatever why attendance upon them should not generally be enforced, we allow that there are cases in which too rigid an adherence to this system might be un-

just to individuals—to talented but poor young men, who, by their own industry and genius, have collected knowledge under circumstances most unfavourable to its acquisition; we trust, that in the improved state of the profession, towards which we are advancing, some provision will be made for such cases, and that the examining board will be invested with a discretionary power of granting an examination and a diploma in those comparatively rare instances where the candidate possesses ample knowledge of his profession, but has been prevented by pecuniary difficulties from conforming to the prescribed system of education.

Foreign Medicine.

Inflammation of the Blood.

IN the August number of a periodical work, entitled "*Traité de Medecine Pratique*," M. Piorry emits the notion of the above disease, to which he has given the name of *hemitis*. He says, "I consider that blood to be inflammatory, the clot of which is covered with a pseudo-membranous layer of varied thickness." Previous to giving this definition, he discusses the value of the buffy coat as a sign of inflammation, and naturally enough decides in the affirmative. But is this coat the intrinsic product of the blood? We think so; yet we have heard M. Bouillaud advance an hypothesis on the subject, which appears ingenious. "The buffy coat," says he, "may probably be the product of a pseudo-membranous exhalation of the internal tunic of the irritated vessels." We, however, allow the inflammation of the blood as the cause of certain localizations; and a long time ago we endeavoured to demonstrate that the efficacy of bleeding in the treatment of inflammation, far from being a support to solidism, argues altogether in favour of the humoral doctrines. Inflammation of the blood is sometimes primitive, but the extensive and intense local inflammations are most certain to give rise to *hemitis*. Inflammation of the blood may occasion local inflammations, and the latter are in turn capable of determining he-

mitis. *Hemitis* may explain that period of incubation with fever, which precedes certain inflammatory localizations. This is certainly theory; but, adds M. Piorry, "theory in this case so closely approximates to the truth, and is so charged with practical results, that some weight should be allowed to it."—*Journal Hebdomadaire*.

[With all deference to the authority of M. Piorry, we are of opinion that the above is straining at a pathological novelty; nor is the "close approximation to the truth" at all evident. We suspect it altogether to be an offering at the shrine of the humoral pathology just now so much in fashion with the French rulers of medicine].

Sulphate of Quinia used in Fever by the Endermic Method.

Dr. Raciborski relates ten cases of fevers, most of which were either relieved or cured by the above remedy thus administered. The conclusions from the details are referable to the following heads:—

1. The sulphate of quinia is capable of being absorbed by the denuded dermis, without losing any of its febrifuge properties.
2. It may be advantageously employed whenever the internal administration is either contraindicated or impossible, as in cases of gastro-intestinal inflammations, spasmodic vomiting, in fretful children, in patients where there is mechanical obstruction to the introduction of the remedy, &c.
3. Though it may be given in such cases in glyster, the facility in producing an absorbing surface, and the energetic action of the sulphate thus used, should lead to a preference of the endermic method, the more as the fecal matters in the large intestine prevent the effect of the salt.
4. There are cases in which the physician is necessitated to adopt the endermic method: of this kind are cases of pernicious fever combined with inflammation of the digestive tube, and accompanied with vomiting and diarrhoea, which would not only be exasperated by the action of the salt, but by throwing off a great part of it, would prevent its acting with sufficient energy to stop the attack.
5. In pernicious fevers free from inflammatory complication of the digestive tube, it would perhaps be better to divide the sulphate into several doses, some to be given

by the mouth, others by the skin, than to gorge the patient with huge doses of it—doses that might produce irritation of the digestive tube, and prevent absorption.

6. Administered in this manner, the sulphate succeeds equally well in all the varieties of intermittent fever: I have seen it cure tertian and quotidian intermittents, and M. Chomel has used it with considerable success in quartans.

7. The medium dose should not exceed four grains at once, but it should be repeated several times.

8. In those rare instances where this dose is not sufficient, it is better to establish several absorbing surfaces of small size, and divide the dose among them, than to apply a large quantity on one surface, because, in that case, the remedy soon produces eschars that prevent absorption, either by their intervening thickness, or by retaining great part of the quinia in their interstices.

9. Accordingly, the blister ought not, at the furthest, to exceed a six franc piece: its locality should not be far from the spinal cord and the digestive canal, and therefore the epigastric and hypochondriac regions are the preferable points for their establishment.

10. At each application the false membranes that form should be carefully removed, in order to make free the absorbing surface.

11. Analogy leads us to think that the endermic method might succeed in all the other diseases in which the sulphate of quinia is indicated.

PERFORATING ULCER OF THE DUODENUM. BY DR. ABERCROMBIE.

A LADY, aged thirty, had been long liable to pain in the right hypochondriac region, which affected her chiefly after meals, and was considerably increased by the motion of her body. On Tuesday evening, 15th November, 1829, she was suddenly seized with most acute pain in that situation, which was soon followed by symptoms of ileus, accompanied with a feeble rapid pulse, and appearance of extreme exhaustion. She lived, however, till Sunday morning, being upwards of one hundred hours from the attack.

Inspection.—There were the usual appearances of most extensive inflammation, with a thick coating of false membrane, covering every part of the bowels, the liver, and the peritoneum lining the

parietes. At the very commencement of the duodenum, close to the pylorus, there was an ulcer, less than half an inch in diameter, with elevated edges, and considerable thickening of the surrounding parts. It was so deep in the centre, that it appeared to have been bounded only by the peritoneum covering the part; and this had given way by a round opening about one-sixth of an inch in diameter. The edges of the excavation itself had that smooth and cicatrized appearance which has often been described in similar cases.

The remarkable feature in this case is the length of time from the attack to the fatal termination. The usual period, in my observation, has been from eighteen to thirty hours, and it appears that some of the French cases were fatal in five or six hours. This difference in the rapidity of the symptoms produced by the escape of fluids from the stomach or intestines into the peritoneal cavity, may be supposed to depend partly on the quality of the fluids. But something would also seem to depend on the state of the parts; and there are facts which would seem to show that a morbid cavity is less affected than the healthy peritoneum. This conjecture seems to be illustrated by a case which I saw during the present season with Dr. Robertson and Dr. Macintosh. The patient was a child between five and six, and the case began with symptoms of chronic peritonitis. After some time, a circumscribed hardness formed round the umbilicus, which gradually became soft, and at last burst. The opening at first discharged purulent matter, afterwards thin feces, and frequently articles of food in a half-digested state, sometimes little changed. The child lived in this state for about ten weeks; and then died gradually exhausted. On inspection, the external opening was found to lead into a large cavity full of feculent matter. This cavity was formed by adhesions between the omentum, peritoneum, and surface of the intestines, all in a morbid condition; and a portion of intestine, high up in the canal, communicated with the cavity by several openings.—*Edinburgh Med. and Surg. Journal.*

—o—

CASE OF BILIARY CALCULUS OF GREAT SIZE. BY DR. OMOND.

On the 17th August, 1830, I found Mrs. S., a married woman, forty years of age, complaining of extreme tenderness of the abdomen, much increased by moving, with the general symptoms of fever, the pulse being full and strong, and the bowels confined. She stated that she had frequent attacks of inflammation of the bowels, the last being a few months ago; that constipation was always a prominent symptom; and that the remedies used were blood-letting and strong purgatives. She is of gross habit of body.

After bleeding, a cathartic prescription was given, containing calomel and colocynth.

18th August.—The blood-letting partially relieved the pain of abdomen, which returned only at intervals. Various medicines have been tried, and all are speedily vomited. Several injections have also been administered, but without effect, not being retained for any time.

19th August.—Stercoraceous matter has been ejected by vomiting to-day, and the symptoms continue urgent as before.

9th September.—Since last report, every medicine tried has completely failed, the stercoraceous matter being still rejected two or three times a day. Strongly purgative enemata have failed to relieve the bowels. Mrs. S. is much weaker, but still takes nourishment daily. The enema-syringe was now employed by the attending surgeons, instead of by a nurse as formerly, and very large quantities of fluid used, to the extent of several basins full. After the third attempt some feculent matter appeared.

15th September.—The pump has been daily used, and the vomiting has ceased. Yesterday a strong cathartic was given, containing seven grains of calomel, and to-day a calculus, about three inches in circumference, has been passed *per anum*.

10th October.—The patient is now able to walk about. She has passed several smaller calculi, and promises to improve gradually. The calculus consists of cholesterine, having the peculiar crystalline texture, and is in the Museum of the Royal College of Surgeons of Edinburgh.—*Edinburgh Med. and Surg. Journal*. —o—

MEDICAL BOTANY.

PLATE VI.—HELLEBORUS.

POLYANDRIA Polyginia.—Nat. Ord. Multisiliquæ, Linn. Helleboraceæ, Juss. Black hellebore. Christmas rose. Radix. Ed. Lond. Dub.

This plant, which was formerly called *Melampodium*, is perennial, and is indigenous in the mountainous regions of the south of Europe, as the Alps, Pyrenees, and Apennines. The earliness of its flowers, which sometimes appear in December, has gained it a place in our gardens.

The roots consist of a black furrowed roundish head (*rhizoma*), about the size of a nutmeg, from which short articulated branches arise, sending out numerous descending radicles, very simple, smooth, brittle, about the thickness of a straw, from a span to a foot in length, deep brown on the outside, white or yellowish-white within, exhibiting 4-6 bundles of vessels disposed around the *medulla*, and of an acrid, nauseous, and bitterish taste, exciting a sense of heat and numbness in the tongue, and of a nauseous acrid smell. These radicles only are used in medicine, and the head and branches are rejected. For the roots of the real black hellebore, those of some conge-

nerous plants are occasionally substituted. The surest way to avoid mistakes is by the herbalist cultivating the plant in his own garden.

Neumann got from 2880 grains 380 alcoholic and 181 watery extract; and inversely, 362 watery, and 181 alcoholic. Its active constituent seems to be of a volatile nature; for it loses its virtues by keeping, and water distilled from it has an acid taste. It has been more recently examined by Feneuille and Capron, who found in it a volatile and a fixed oil, resin, wax, a volatile acid, bitter principle, mucus, alumine, super-gallate of lime, and of potass, and an ammoniacal salt.

Medical Use.—In large doses hellebore root is a drastic purgative; in smaller doses, it is diuretic and emmenagogue. It has been used as a purgative in cases of mania, melancholy, coma, dropsy, worms, and psora, and as an emmenagogue. But its use requires very great caution, for its effects are very uncertain, and affected by many circumstances.

It may be exhibited in the form of extract, although its activity be much dissipated by the preparation. An infusion and tincture certainly promise to be medicines of more uniform powers. Willdenow says, that the black hellebore of the ancients is his fifth species, the *Helleborus orientalis*, the *H. officinalis* of Salisbury and Sibthorp.

By JAMES MANBY GULLY, M.D.

LECTURE XVIII.

Various phenomena of Acute Gastritis—Necroscopy.

THOUGH I have shewn that inflammation may traverse the whole course of the intestinal canal, from the stomach to the rectum, you must not imagine that it necessarily follows that course, and that there is an entity called gastro-enteritis necessarily commencing in the stomach and necessarily terminating in the colon. The reverse may take place, and the inflammation proceed from beneath upwards: in that case, after a few days of colic, which may be strong enough to cause the name of dysentery to be applied to the disease, the inflammation rises into the small intestines and as far as the stomach, and the accompanying symptoms of enteritis in the first instance, and then of gastritis predominate. This leads me to exhibit inflammation, commencing in the lower portion of the digestive canal. It may be in this manner developed, in consequence of improper diet; the patient then has colics, accompanied with obtuse sensibility of the belly: a difficult and painful but not excessive diarrhœa attends; the appetite is not deranged; there is little or no meteorismus. This state may continue from three to twenty days: I had a patient the day before yesterday, in whom it had persisted twenty days. Generally speaking, and especially among the poor, no pursuit is stayed by it; it is looked upon as a simple complaint, because it does not prevent their eating and going about their occupations, until it obliges them to go to bed; whereas among the rich, who attend by times to their slightest ailments, it is more easily remedied. Those who neglect these colicky pains and diarrhœa, suddenly fall ill, and have malaise, fever, prostration, head-ache, great lassitude, ardor that seems to evaporate upwards, sinister presentiments, &c.; they are found to take to their bed with

acute gastro-enteritis. Should the inflammation of the lower portion be inconsiderable and predominate in the upper part, the purging ceases, and is wanting throughout the disease. Should the stomach be stimulated, it is possible that ataxic symptoms may come on, and the patient die without the return of diarrhœa. Perhaps the autopsy will give no sign of this diarrhœa, which was the primary disease; but if you are capable of judging of the value of cadaveric lesions, you will readily comprehend why it has not re-appeared, and why you see no traces of it; the fact is, that a revulsion from the lower to the upper portion has taken place; but death rarely happens in this case. Most frequently the inflammation of the upper portion is remedied by mild drink, and, after four or six days, the diarrhœa is re-established and remains the predominant phenomenon; and the probability of this will be greater the longer the affection has existed previously to the acute stage.

Thus we may have two forms of diarrhœa in acute gastro-enteritis; one proceeding from above, the inflammation having travelled from the cardia to the anus: it does not appear until after twelve, twenty, or more days of the acute febrile state, and when the gastro-enteritis has not been arrested; another, which has commenced from below, has been stayed for some time, during which the inflammation has predominated in the upper portion, and returns when the descending inflammation reaches the ileo-cæcal region. There are cases in which the higher inflammation is not sufficiently intense to stay the diarrhœa. Thus, a person who has diarrhœa in the first instance may have it suspended or not, but he will always have it suspended when the gastro-enteritis is in a high degree, and he never has it when the upper inflammation does not supersede the lower.

A third form of diarrhœa may obtain, but is less common than the preceding. I allude to patients who have neither colitis nor gastritis, but whose principal point of irritation is in the right hypochondrium. In that case the duodenum is the point most commonly affected; there is pain of the region occupied by this organ, a pain that may be propagated to the liver, while bile is

frequently poured into the stomach; there is a certain degree of meteorismus and tendency to shivering and heats, especially after eating and during the second stage of digestion; there is neither diarrhœa nor vomiting, and ultimately fever is exhibited, with redness and dryness of the tongue, thirst, frequent pulse, restlessness, &c. In this case the patient either continues without diarrhœa, the inflammation predominating above; or he has it as soon as the inflammation, which travels downwards, has passed the ileo-cæcal valve. Meteorismus without diarrhœa shews that the inflammation has reached the end of the ileum; the appearance of diarrhœa marks the period when it has passed the valve.

All these combinations are possible. To lay down an invariable march in acute gastro-enteritis and to characterize it exclusively by such and such symptoms is to run the risk of never understanding it at all. Therefore it is that I have exhibited inflammation to you as coming, going, and pursuing all manner of routes in the digestive tube; it is the natural method, for it is following nature step by step.

Would you now that I should enter upon the probabilities and describe what symptoms characterize the first, second, and third forms? The first, that which commences from above, attacks in preference persons that have been abusing stimulants, but stimulants of a bitter kind; the same is often the case with regard to the second form; the third more particularly affects those who have been subjected to bad food, who have neglected the consequences of purging and bad digestion, and who have gone on heaping food in the stomach in spite of previous indigestion. M. Scoutetten has made some interesting experiments on this subject. By means of aliment of an exciting but superior quality, combined with irritating alcoholic fluids which exalt the sensibility of and redden the mucous membrane, he induced gastritis and gastro-enteritis without diarrhœa, in animals; by means of indigestible, spoiled and putrid food, and the concurrence of cold and humidity, he produced the same diseases in the secreting degree, and with diarrhœa. In the former case the villousities and sanguineous network of the digestive canal were specially affected; in the latter the mucous follicles and the entire exhalant and secretory system suffered more from the inflammation than the properly called mucous membrane. These, be it remarked, are very important distinctions.

Let us pause on the additional phenomena of gastro-enteritis. Inflammation rarely remains limited to the digestive canal. It is ever tending to gain space and even to propagate itself, is always active and predominant when nothing has been done to stop it, and, *a fortiori*, when improper means have been used for that purpose. This very mobility it is which gives the physician so

much power in combatting it, and is far from reducing him to a purely speculative and passive condition, as has been affirmed; in the majority of cases he can do whatever he pleases with it, provided he has sufficient talent.

The most ordinary additional or disseminative symptoms of the primary irritation are—1. The redness and dryness of the tongue, with the alteration of the mucus it secretes. These symptoms, which I call organic sympathies, may be considered as the repetition of the inflammation of the digestive canal, and go on to the production of aphthæ and ulcerations. 2. The same phenomena in the pharynx and larynx are explicable in the same manner. 3. The irritability of the skin; this may amount to inflammation. 4. That of the bladder is liable to a similar result. You may conceive of all these phenomena by the various ways in which the inflammation shews itself. You see wherefore some individuals have difficulty in swallowing, the inflammation proceeding from the cardia to the pharynx, and wherefore others have none; wherefore some have cystitis, while others are free from it, &c. When inflammation is badly managed, it may find its way to every part, and cause the most frightful ravages at a distance from its primary focus; I have seen it, in openings of the mucous membranes, in the pharynx, in the genital organs, become rapidly gangrenous. 5. The nervous phenomena; these are of the first importance, and you cannot too closely consider them; whenever there is an acute inflammation of the digestive canal, you may be certain that the nervous centres will be unfavourably influenced by it. In the slightest degree there will be restlessness and alteration of the affective faculties; frequently the acts of the patient can scarcely be recognized; a man who only appeared to be prudent will become pusillanimous when gastro-enteritis takes possession of him. Inflammations of the lungs never give him the smallest mental inquietude, unless he be a physician who is aware of the jeopardy in which he stands. The more intense and extensive gastro-intestinal inflammations are, the more sinister are the presentiments: if it descends to the lower portion, the patient will return to himself, will come out of his stupor, and will have hope, though there be still considerable fever: you behold another man, and this change occurs immediately upon the inflammation ceasing to predominate in the superior portion, that is, in the stomach and small intestines. It is not true that the cerebral symptoms are connected exclusively with the alterations of the mucous follicles prevailing in the ileum. When these symptoms exist simultaneously with layers of thin inflamed follicles it is invariably because the upper portion is affected at the same time; the moment the inflam-

mation has left it and descended to the lower portion, the nervous phenomena, the terror, presentiments, delirium, stupor, subsultus tendinum, disappear, and, if the patient dies, you behold him expire calmly, full of hope, and in the belief that all he requires is strength.

Three great divisions may be established in the influences exercised by phlegmasia of the digestive canal on the nervous centres: those of the upper part act on the brain; those of the middle portion on the spinal cord; and those of the lower region, the two extremities of the colon inclusive, on the lower portion of the cord. With moderate irritation of the colon, a man may be gay, whereas, if a like irritation be in the stomach, he never fails to be sorrowful: with colitis only he will even fall into *inartasmus*, and not perceive it: if he becomes anxious and restless, it is because the inflammation has risen upwards; a fact that you may verify by reference to all the histories of epidemic dysenteries. Let us enter into the distinction of the nervous phenomena themselves.

We have seen that the first of these are restlessness and headach. In general, the latter does not continue: after antiphlogistics it scarcely ever continues beyond two days, unless there is predisposition to inflammations of the brain. Follows delirium, which is a modification or higher degree: the disease is then serious. The inflammation of the stomach, of itself, may produce delirium, but the latter is more intense, and more or less furious, if the small intestine is at the same time inflamed. After it comes stupor. These two phenomena often go together, but the delirium without stupor is not the same as that with stupor: the former is unaccompanied by *sordes*, acrid heat of the skin, and prostration: while the latter has the acrid heat, greater dryness of the tongue and throat, more decided suffusion of the eyes, brown tongue, and frequently also startings, and subsultus tendinum, twitchings that may first of all be detected in feeling the patient's pulse, and which prevail in most of the muscles of the body. They are in proportion to the quantity of irritation sustained by the spinal cord, for it is impossible to have acute phlegmasia of the small intestine without the cord becoming affected. You may say, that as the colon also communicates with the cord by nerves, it may cause the same phenomena; but no, when that viscus alone is disordered it does not produce it—the small intestine must also be implicated, or even the upper region of the digestive canal.

Here, then, are two forms of delirium, one ataxic, the other adynamic: the former not necessarily accompanied with symptoms announcing excessive inflammation of the digestive tube, the latter exhibiting them all. What induction are we to draw? why,

that the brain has become more disordered than the digestive canal. Yet think not that this canal is no longer affected: I will explain this; men contract particular irritations of the digestive canal in the gastro-duodenal region, and bear them for a longer or shorter period before they pass into the acute stage: at length they do pass into it: the nervous phenomena suddenly become predominant, and, sometimes in two days, these persons sink before the gastro-enteritis has had time to develop itself and pass through its periods: you open his body, and you are altogether astonished to find, together with the engorgement of the brain, either an intense duodenitis or a considerable gastritis. Another person has pains of the belly, irregular diarrhoea, and meteorismus: fever, with ataxic symptoms, comes on: the death is as prompt as in the former case: you find a phlegmasia, with ulceration and thickening of the end of the ileum, together with a gastritis or gastro-duodenitis. If the febrile state is prolonged, and there is adynamy, *sordes* &c., all these disorders co-exist, but the irritation of the brain has not been so vehement as when the patient sinks in a few days in a state of ataxy.

What follows from this? First, that the ataxic form is a sign of the tendency of the brain to inflammation of its periphery, or, as it is called, arachnitis—an improper expression, for it is the pia mater that is the seat of the phlegmasia, the arachnoid being only secondarily affected. It next follows that the adynamic form includes the cases where the inflammation of the digestive canal predominates over that of the brain, is more extensive, more intense, more particularly established in the small intestine, and where the brain is rather gorged than inflamed. Intoxication gives you an idea of this condition: you behold congestion of the brain proceed in the same manner as congestion of the digestive canal. In asphyxia, and poisoning by carbonic acid, especially by that which is impure and is the product of the combustion of coal and wood, and contains several other gases, you see the same thing. Thus, the three states of intoxication, asphyxia, and adynamic gastro-enteritis, though not completely identical, have much connexion with each other.

The groups of ataxic and adynamic symptoms separately, are as follow:—In the former the patients, after suffering for some time in the digestive canal, particularly in the upper portion of it, have fever, with delirium: in a short time you behold them exalted or furious, with fiery eyes, not much fever, and no dryness or blackness of the tongue. These patients frequently die when you least expect it, and this it is that has caused the name of malignant to be given to this shade of the disease, in opposition to that when it goes on more regu-

larly. If you calm the cerebral irritation, the ataxic group is dispersed, and the gastro-enteritis falls into its ordinary progress, and may even exhibit the adynamic train of symptoms. This train, which announces a general sanguineous congestion of the brain, rather than a tendency to vehement inflammation of its periphery, is manifested either in the commencement or in an advanced stage of the gastro-enteritis. In the beginning it is manifested in full-blooded persons, who have been stimulated, and from the onset have had a large portion of the digestive canal inflamed. The face is of a dull red, livid colour, the tongue brown, the mucus on it blackish, and the teeth encrusted with a soot-like matter. Some have said that this is owing to the patient breathing by the mouth alone; but if this were all there would be merely a dryness that would soon disappear, and not that fuliginous substance, which is diseased mucus, and a sanguinolent oozing that is remarked in the digestive canal as well as in the mouth, the only difference being that in the latter locality they are not dry. At the same time the physiognomy changes and shrinks; the patient is indifferent to everything passing around him, being sunk in stupor and prostration, and only replies briefly when spoken to: he is shaken by convulsive movements, and mutters incessantly in a state of low delirium; whereas, in the ataxic condition, he talks nonsense, and tosses himself about like a lunatic, so much so, that his state might be mistaken for that of an insane person. As the adynamy gets on, the patients, instead of being restless and watching as they were at the onset, become more and more apathetic and prostrated; the eyes sink, become dull, and an impeded state of the respiration supervenes, which is the commencement of the agony, and the prelude of death. All this displays to you a general congestion of the encephalic substance, proceeding in concert with the congestion of the digestive canal, and destruction of the mucous membrane of the stomach, and of itself capable of becoming predominant and carrying off the patient.

Let me not be thought tedious if, after these details, I bring together into a summary the phenomena of acute gastro-enteritis: it is a mighty subject, and involves great pathological considerations.

We have shewn the different progress of inflammation in the three regions of the digestive canal, where we have seen it rise and descend from one to the other, and starting from the middle portion, take either or both directions. We have endeavoured to point out the particular influences under the operation of which this or that progress is pursued. In fact, there is no reason why an inflammation should always proceed in a fixed direction, just as there are no epidemics in which the organs are affected in precisely the same manner, the same order,

and the same succession. This it is that has always rendered classifications extremely difficult so long as it was attempted to characterize diseases according to groups of symptoms, whose number and order varying infinitely, a confusion ensued, which it is our duty to clear away. We insisted on several points, particularly the nervous, ataxic, and adynamic phenomena. Death always occurs by the presence of these phenomena, or rather by the nervous system—inflammation of the digestive canal is not of itself sufficient to kill: here is an instance of it. A robust man, who resides near to me, was kicked in the belly by a horse, and died on the spot. He had the small intestine cut through without the occurrence of any hæmorrhage, the vessels being contused, and, as it were, beaten down. This man died by the nervous system. In fact, when a person does not die from hæmorrhage, from impediments to the circulation of the blood, from asphyxia, from gradual exhaustion of the powers, it is in this manner that he does die: nor to that end is it necessary that the nervous system should be the seat of an excessive congestion, of effusion, hæmorrhage, induration, or solution of continuity. There are inexplicable but undoubted modifications of the nervous system, by which a gastro-enteritis, for instance, that appears to come on under not very unfavourable circumstances, becomes mortal in a very few days after taking on a malignant or ataxic character, either in consequence of the subject of it being ill-disposed and too irritable, or because he has been deprived of the principal vivifiers, pure air and proper food. Whenever a gastro-enteritis, a peripneumony, a fever consequent on a vivid inflammation, attacks an individual who has been confined in prison, it often happens that this individual is as it were struck by lightning: so also of one who has committed excesses and inordinately stimulated his nervous system.

We reduced to two forms the mode in which inflammation of the digestive canal affects the nervous matter; one ataxic, announcing an irritation of the periphery of the brain, approaching to inflammation; the other adynamic, shewing the cerebral congestion proceeding, step by step, with that of the digestive canal. Great varieties of the former exist, all which we have not laid down, but which have acquired for it the names of ataxic, malignant, irregular, &c. In fact, according to the point of predominating inflammation, you have convulsions, delirium, priapism, ejaculations, &c. Leaving this theatre the other day, a person told me he had recently witnessed this latter fact. I myself have seen patients who masturbated during gastro-enteritis, having, no doubt, a predominant phlegmasia of the cerebellum or the spinal marrow.

As the patient necessarily dies from the nervous phenomena under an ataxic or

adynamic form, this event takes place—sooner if the morbid cause is active, if the disease has been improperly combatted, and especially if the individual in whom the gastro-enteritis is developed already bears about him a point of phlegmasia that has disorganized the brain or digestive canal—later, if he is in more favourable circumstances. The first form appears early; the second after five or eight days, the disease passing from the bilious and gastric aspect to the adynamic. Thus a patient may sink at all periods, from the first twenty-four hours up to the tenth, twentieth, or even the hundredth day: there is no certainty whatever on this score. Sometimes these forms lapse into chronicities. When the disease is prolonged to the utmost, the ataxic and adynamic phenomena disappear—and well they may, for it would be impossible to live on with them.

Necroscopy of Acute Gastro-enteritis.—When patients sink in the commencement of gastro-enteritis, a chronic phlegmasia is ordinarily found, upon which an acute one has ensued. The traces of it in the stomach are redness, thickening of the mucous valves or folds; in the duodenum, the same phenomena, with elevations and congeries of smaller glands; in the intestines, redness of different shades, and brown spots of varied extent. In all these localities the mucous membrane may be, at distances, softened, worn, or completely destroyed: even the muscular coat may have disappeared, and this is more especially observed when the disease has been of very long duration. The duodenum is frequently found blackened, thickened, sometimes deeply ulcerated; the liver enlarged, yellow, gorged with blood, projecting beyond the edges of the ribs, or adherent by bands to the serous membrane; the bile disordered, having lost its natural colour and become black, muddy, thick or more clear than usual, and like serosity: these disorders are more particularly met with when the individual has died of gastro-enteritis developed upon a chronic duodenohepatitis: or he may have died of a gastro-enteritis coming on after an ileo-colitis of varied duration. A considerable degree of redness is then discovered in the ileum, its mucous membrane is hypertrophied, its agglomerated mucous follicles deeply ulcerated, and in the cæcum so great is the thickening of its internal membrane, and, indeed, of all its coats, that one might almost fancy it to be cancerous degeneration. At the same time the corresponding ganglions are swollen, red, and greyish, announcing that irritation had existed for a long time in those parts, and had passed into the sub-inflammatory state. This disorder is frequently present while the rest of the canal is red, and only exhibits the incipient characters of acute gastro-enteritis. In these cases, although the individuals have perished with cerebral phenomena,

nothing is found in the brain, and this has led some practitioners, since the frequency of autopsies, to attribute the nervous phenomena to these alterations of the digestive canal, whilst those who have maintained the existence of a particular form of gastrointestinal affection, to which they have given the name of *dothinentery*, have laid these phenomena at the door of the follicular appearances. This is the state of things when patients die in the first period of our sporadic gastro-enteritis, that is, in six, ten, or twelve days; such persons had previously carried about a chronic gastritis, duodenitis, enteritis, or ileo-colitis, had had exaggerated sensibility of the stomach or duodenum, calicis or diarrhœa, and had neglected or stimulated them. A mixture of acute and chronic alterations is then observed; the parts that were not chronically affected are not softened nor diffuent, exhibit no brown or red colour, no fetidness nor meteorismus, and no livid nor slate-coloured aspect.

Thus you have to consider the traces of the acute and of the chronic stages, and you may meet these two forms separately; in fact, a patient may die of acute gastro-enteritis without having previously had the chronic form of that disease. In our military hospitals, where men of impatient spirit, and little accustomed to be stoical in suffering are seen, and others again, in whom sorrow and despair soon produce a disgust of life, some are met with who throw themselves out of the window during the first periods of a gastro-enteritis. It is then observed in the same character that it is possible to produce it withal in the healthy animal, with the mucous membranes red and thickened, but sound in structure, and not at all softened into a jelly, with elevations, injected vessels, and swollen, but not yet diffuent follicles. Similar alterations may be observed in an individual who dies after taking an acid or alkaline poison; with the exception of those places where the substances in question may have produced eschars, where you will find an intense, vinous, uniform, spotted or striated redness, with more or less thickening of the mucous membrane, vehement contraction of the muscular tunic, narrowing of the intestine, no fetid odour, no mucous flux, nor watery or bilious congestions.

On the other hand, a man may die of chronic gastro-enteritis before it has had time to pass to the acute stage, and by itself prove fatal—if for instance, he dies after taking an excessive quantity of spiritous fluids, or a narcotic poison that does not kill by inflaming. In such a man you will find a thickening of the mucous membrane, rugosities, dark-coloured points, brown patches approaching more or less to black, &c. If this individual has had fever, and an acute inflammatory state that has lasted for some time, besides the traces of such a state, you

will see the same parts blacker, more softened, disorganized, and diffuent, the ganglions red and inflamed in the places corresponding to the new inflammation, and thickened, hardened, greyish, or whitish in the points corresponding to the old inflammation. All this is visible when people are willing to see it, and I have demonstrated it a thousand times; for I still practise pathological anatomy in order to make it physiological.

[The immense importance of the questions involved in the study of the gastro-enterites, affords ample excuse for any prolixity that may appear in this portion of the lectures. In fact, when it is considered that on this point hinges the question of the long series of pathological phenomena, that collectively go by the name of fever—whether those phenomena be symptoms of one circumscribed irritative cause, or of an irritation in every locality of the body—it is one worthy of the most patient attention, and on which to be prolix is to be judicious. To occupy the reader therefore, during four or five lectures with the facts and arguments on which M. Broussais' doctrine of fever is founded, will be only doing bare justice to the subject. I have carefully condensed the matter that was absolutely necessary to the development of that doctrine, and have rigorously excluded all that does not strictly bear upon it; and having done this, I call upon the reader to investigate the learned lecturer's propositions with a critically searching, yet impartially judging spirit.—J. M. G.]

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN.

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho:*

Session 1834-35.

LECTURE LI.

—

*Vices of Conformation, and Intra-uterine and
Extra-uterine Diseases of the Respiratory
Apparatus.*

GENTLEMEN—The respiratory apparatus includes the nasal fossæ, the glottis, larynx, trachea, bronchiæ, lungs, pleura, and chest.

Some persons would be surprised at my including the nasal fossæ among the organs of the respiratory apparatus, as they are the seat of olfaction, or smell. It is true that they are only accessory to the organs of respiration, and are distinct from the air passages in fishes; but it is to be recollected that the infant respire through them when

sucking, and generally while it sleeps. It would be impossible for the infant to suck for any length of time unless it breathed through the nostrils, and for this reason I include these among the organs of the respiratory apparatus, though they are the seat of smell.

On examining the embryo before the sixth week of uterine gestation, we find that the nose does not exist, and that the nasal fossæ communicate with the mouth. About the sixth or eighth week they become defined. The nose, like all other parts, may be imperfectly developed, or entirely absent (Larue), or its place supplied by a fleshy prolongation, which may descend over the mouth (Garnier, Billard); or the nose may be bifid (V. Laroche, see Billard).

At birth the pituitary, or mucous membrane, is always very red and engorged; it possesses great sensibility, which is proved by the sneezing of infants immediately after birth. This membrane rapidly secretes an abundant mucosity, which is discharged continually from the nose of some infants. The sanguineous congestion, the irritability, and abundant mucous secretion of the nasal mucous membrane, demonstrate its great tendency to inflammation, and explain the frequency of coryza, popularly termed "cold in the head," of new-born and very young infants. This disease is common in spring, autumn, and winter—seasons in which the temperature is most variable, and epidemic catarrhs are common—unless the lying-in chamber be kept warm, and is often induced by the imprudence of nurses in exposing infants to cold, by removing them from the mother to distant parts of the house.

Coryza of new-born infants may be simple, or confined to the nose or throat; or it may be succeeded by the formation of a membraniform concretion throughout the whole extent of the nasal fossæ.

Simple Coryza.—The influence of cold, humid air, coldness of the extremities caused by the urine, when the mother or nurse neglects to change the infant and put on warm, dry clothing; exposure to the heat of a strong fire, or to the light and heat of the sun, are the commonest cause of coryza in infants. The disease is generally caused by the imprudence of parents and nurses, who suddenly remove infants from very warm to cold apartments, or put them to sleep in the latter, or place them in cold or icy baths, on the mistaken grounds of strengthening them; or clothe them too slightly in cold, humid weather, when they are sent into the open air. The experience of every one proves that all causes which suppress transpiration or insensible perspiration, injure the strongest adults, and consequently must affect more severely infants of a tender age. It is known to every physiological physician that the best means of preserving infants and delicate persons

from the diseases which result from changes of temperature, is to accustom the individual insensibly to the open air.

The symptoms are constant sneezing and a discharge of a limpid, yellow or green mucosity from the nostrils. The infant, contrary to its usual habit, sleeps with the mouth open, it sucks with difficulty, as its respiration is impeded, and its snuffling is more or less intense. In some cases the mucosity is so thick as to close up one or both nostrils, and then the deglutition, or function of swallowing, is more or less difficult; the eyes are red and humid, the infant is restless, it cries, and its countenance is expressive of pain and suffering. If it is presented to the breast under these circumstances, its anxiety and sense of suffocation are very much increased; it is instantly compelled to abandon the nipple, because it cannot perform suction, as it can only respire by the mouth, and this is filled by the nipple and milk. It is harassed with hunger, which it cannot satisfy, and soon becomes debilitated and emaciated; but it generally dies before the latter condition is extreme. When this species of catarrh is intense, accompanied by fever, increased in the evening and night, and succeeded or preceded by shiverings, the disease is intense.

In some cases the symptoms advance very rapidly, and a young infant may die in two or three days. This disease may be acute or chronic; it gradually abates and then disappears. It may be complicated with determination of blood to the brain or lungs, with otitis, ophthalmia, quinsey, pulmonary catarrh, &c. The disease is therefore to be considered as most dangerous to young and delicate infants, unless it be properly treated. The danger of the disease is to be estimated according to the severity of the symptoms and rapidity of their progress, the degree of tumefaction of the affected membrane, the abundance and consistence of the mucosity, and the age of the infant.

When the inflammation is slight, the mucus natural and sparing, the respiration and deglutition very slightly affected, the prognosis is favourable.

The disease is not dangerous unless it extend to the throat and chest, when coryza is slight, or terminates by resolution; but by an injudicious treatment, it may end in a chronic form, and then ulceration succeeds, ozena, and caries of the nose, and, finally, gangrene may supervene; terminations which are, however, extremely rare in infants. But when inflammation is intense, the respiration and deglutition greatly impeded, the face red or purplish, the pupils dilated, and cerebral congestion manifest, the prognosis is unfavourable.

In some cases, inflammation of the nostrils is succeeded by pseudo-membranous concretions, which line the whole surface of the nasal fossæ. M. Billard informs us, that in forty infants affected with coryza,

five had false membranes, which were arrested by the larynx, though the mucous membrane was intensely red, thick, and very friable. The formation of this membrane was preceded by the usual symptoms of coryza, and it was bathed with thick mucosities. The infants thus affected rapidly perished; and in one only was the membrane detected in the nostrils during life. In others the mucous membrane was softened, and had undergone ramollissement.

Treatment.—When coryza is recent and slight, it is easily removed by heat and regimen, and medicines are seldom necessary, or, according to M. Capuron, are more injurious than useful. The infant ought to be kept in a warm temperature, its bowels opened, and ass's cow's or goat's milk administered to it. When very young, it cannot suck the breast, as suction is painful, and increases the difficulty of respiration. If the deglutition is very difficult, the powers of life ought to be supported with nutritive clysters, composed of chicken broth, beef tea, mutton broth, &c. When the respiration cannot take place through the nostrils, almond oil may be dropped into them; but, as they are both short and straight in early life, the application of humid vapours is injurious, and only increase the difficulty of respiration. In such cases, nurses perform a most disgusting operation, "sucking the nostrils," acting perhaps on the ancient axiom:

"Nihil turpe aut fœdus, quod humano generi pertinet;"

the free translation of which is, that, "nothing is base or unpleasant, which is capable of relieving humanity." A leech or two may be applied to the root of the nose, or behind each ear, as congestion of the brain or apoplexy is to be dreaded. The excitement of counter-irritation in the intestinal canal by calomel, castor oil, &c. is highly beneficial. The application of a blister to the nape of the neck, between the shoulders, or to the arm, is also useful.

When cerebral congestion is present, leeches behind the ears, purgation, warm baths, and counter-irritants are indispensably necessary. Diaphoretics and diuretics are also extremely useful.

When an adventitious or false membrane is formed in the nasal fossæ, we should employ the same remedies as in croup, when similar membranes are dreaded, or in the course of being developed. In such cases, the insufflation into the nostrils, of calomel, powdered alum mixed with sugar, has been recommended. Care must be taken that the powder used is not passed into the larynx, which would excite coughing, and greatly aggravate the disease and all its complications.

Maternal lactation ought not to be allowed for the reasons already stated.

When coryza is followed by ozena, or ul-

ceration, accompanied by extreme difficulty of respiration and deglutition, and a florid or purplish countenance, with cerebral or pulmonary congestion, it has been designated "malignant snuffles by nurses." In such cases the whole of the treatment already recommended must be employed, and will often succeed in effecting a cure, although the disease may be considered malignant or fatal. Some authors advise issues and setons in the neck; injections of the solution of chlorurets of soda and lime properly diluted and combined with opium, thrown into the nostrils with an ivory or bone syringe; in fact, the usual treatment for *ozena*. Such cases are, however, of very rare occurrence. *Coryza* is generally cured, if treated early, by the means already recommended.

Vices of Conformation and Diseases of the Glottis, Larynx, and Trachea.—The glottis has been found very much contracted, and sometimes obliterated, in new-born infants. Dr. Rossi describes a case of obliteration in a male infant of good external conformation and of ordinary size. The infant moved its lips, and also its limbs in different directions, without having ever breathed, and the heart and arteries beat with the usual force.

In other cases the glottis, larynx, and trachea were filled with tenacious mucosities; and these caused asphyxia in some. In one case the glottis was found straight, and closed by a strong membrane which was produced by the mucous lining of the affected part. The trachea was pervious, but the bronchiæ were obstructed by a cartilaginous substance*.

The glottis, larynx, and trachea are not developed before the second, and sometimes the third month; but are fully formed between the sixth and eighth month. The mucous membrane which lines these parts is of a roseaceous colour, but this is less vivid in the trachea, and is often covered with mucosities at birth. The vices of conformation are smallness of the glottis, epiglottis, larynx, and trachea, which may impede the voice, speech, and song in after life. The rings of the trachea often vary in size.

The mucous membrane of the preceding parts has been highly congested, and even effused blood, during intra-uterine life, as observed by M. Billard, but he never saw it inflamed. He often observed the larynx and trachea filled with mucosities, which in his opinion might impede the establishment of respiration. I have repeatedly seen this state of disease, and so, I presume, has every practical and observant obstetrician. In such cases the cry is stifled, there is a mucous rale or rattle in the throat, the voice is hoarse and often nearly suppressed. The sense of suffocation impels the infant to make strong efforts to relieve itself; it

coughs and expels the mucus from the wind-pipe, but as it does not possess the power of expectoration, it swallows the fluid expelled into the fauces or throat, from which it ought to be extracted by the obstetrician with the finger. Lastly, there may be dark, violaceous spots or petechiæ on the mucous membrane of the trachea and bronchiæ.

Diseases developed after Birth.—The forms of disease which may affect the larynx of the infant at the breast are congestion, inflammation, œdema, ulceration, and gangrene.

Congestion.—The larynx is almost always congested in new-born infants, continues for some time, and gradually disappears. The mucous membrane of the larynx in infants from two to four months, is of a pale rose colour. It is always easily congested, and more especially by all causes that induce asphyxia. It may also be the seat of ecchymosis, as well as the mucous membrane subjacent to it. In some cases the ecchymoses were so marked that it was supposed some violent external violence, such as strangulation, had been applied. In some cases blood was found effused on the larynx and trachea, and was coughed up by the infant, or escaped from its mouth and nostrils.

This is particularly remarked in infants whose skin and cellular tissue was œdematous or hard, and who manifested a general plethora.

Angina—Laryngea-laryngitis.—Inflammation of the larynx is sometimes observed in infants, but is most common at the adult age. The disease is simple erythema, or is succeeded by the formation of a membrane.

The erythematous laryngitis may be slight or intense, and may be accompanied by tumefaction, pain in the part, laborious breathing, a red or purplish hue of the face, ramollissement, and ulceration of the mucous tissue.

The causes of this disease are exposure to cold and moisture; as when the cold wind blows in the face of an infant or child, either on foot or in the nurse's arms; cold applied to the feet, or long continued crying, or the existence of inflammation in some other portion of the mucous membrane of the respiratory organs, as of the nasal fossæ (*coryza*), or trachea (*cynanche trachealis* or *trachitis*).

When the voice of the infant is hoarse, or nearly suppressed, the disease is situated in the upper part of the larynx, or the middle of the tube. The inflammation may be more or less intense, and be accompanied with a secretion of white, transparent, yellowish, or puriform mucosity, and then the respiration is very much impeded, the blood cannot return from the brain, and cerebral congestion may speedily follow.

Laryngitis may be simple, or succeed other inflammations, as *coryza*, *trachitis*

* Journal des Progrès, t. iv.

and bronchitis. The progress of the disease is generally rapid, and often obscure at the commencement; but when it is intense, the characters of the altered voice are sufficiently diagnostic, and if we examine the fauces or throat, we often discover a blush of inflammation, which, in some cases, extends into the œsophagus and larynx. In such complications there may be vomitings of mucosities, secreted by the mucous membrane of the fauces, œsophagus, and larynx; but this symptom is seldom present in simple laryngitis.

In the last form, the infant can seldom suck the nipple, and the pain caused by the movements of the pharynx in the act of deglutition, excites vomiting, and the fluid sometimes regurgitates into the larynx, and may produce suffocation. The result of disease in such cases may be congestion of the brain and lungs. It is important to mention, that when laryngitis is accompanied by an abundant copious secretion, there is danger in placing the infant on the back during repose, as it may be suffocated by the reflux of the mucus into the larynx, unless the infant possess sufficient power to cough it into the fauces, which is seldom the case with new-born or very young infants. I may also observe, that when the glottis is narrow and straight, inflammation may be followed by a degree of tumefaction or œdema, which may prove fatal. I have attended four infants destroyed in this manner. In such cases the face becomes very red, livid, or purplish, the nostrils expand, the respiration is extremely difficult and laborious, often impeded by spasms of the respiratory muscles, a convulsive motion accompanies inspiration, and may be observed in different parts of the body during the expansion of the thorax, and this is often intense in very young infants. This form of disease has been termed *suffocating angina*, and is closely allied to the *spasmodic croup* or *asthma* of infants (Miller, Clarke, North, Marsh, &c.), which I shall immediately describe. M. Billard states that in such cases he often found the cavity of the larynx filled with an abundant thick mucosity, and which caused such obstruction as to induce asphyxia. I may here observe, that laryngitis is a most fatal disease both to adults and infants.

Treatment.—When laryngitis attacks infants at the breast, it will be necessary to advise the mother or nurse to allow it to suck for a very short time, and if possible without avidity. It may be applied frequently, but for a very short time. If the respiration and deglutition are difficult, it is best to suspend the lactation altogether; to apply two or three leeches to the larynx or trachea, the number to be determined by the age and strength of the infant, or below the clavicle. After the leeches fall off, the bleeding is to be encouraged by fomentations with warm water, and it will be carried

to a sufficient extent, when the face becomes pale, the eyes half closed, and the superior and inferior extremities are colder than natural. But unless the breathing is improved and the symptoms diminished, a mustard fomentation, or a thin poultice may be applied over the larynx or upper part of the wind-pipe for five or six minutes; or a blister may be allowed to remain on for two or three hours, but no longer. The infant ought to be bled from the back of the hand or instep, if necessary, and then placed in a warm or tepid bath for five or six minutes; the bowels are then to be opened with two or three grains of calomel, a teaspoonful of castor oil, followed by half an ounce of manna dissolved in milk. When there is cerebral congestion, a leech ought to be applied behind each ear, the infant put in a warm bath, with a napkin or cap wetted with cold water applied to the head, while the body is in the bath, and mustard fomentations, or cataplasms applied for the space of time already mentioned, to the legs and feet, and leeches or cupping employed on the nape of the neck or between the shoulders. These are intended to disgorge the capillary system of the skin, but ought to be applied at some distance from the inflamed part (Sabatier, Ware, Graves, Copeland, &c.), or over it, according to the general opinion. I agree with the authors first named; and have often observed that leeches did harm when applied over a superficially inflamed part. Thus, if applied on the inflamed skin they increase the quantity of blood in the subjacent part, a fact well exemplified by Dr. Loudon, of Leamington, who applied a leech or two every second night to the mammae in amenorrhœa, and caused the breasts to enlarge to an immense size. Here I must refer to my observations on infantile therapeutics, for an account of the cautions necessary in employing leeching, general bleeding, cupping, blistering, and counter-irritation in diseases of infants.

Home, Crawford, and others, have strongly advised emetics of ipecacuan or antimonial wine, or of the preparations of squills in trachitis or croup of infants, on the grounds of exciting a diversion or counter-irritation, and facilitating the expulsion of the mucosities or false membranes from the larynx, trachea, bronchiæ, and remaining air-passages; and others prefer purgative clysters, the foot bath, fomentations, and blisters to the chest or between the shoulders. There are some, and I am of the number, who order the face, nape of the neck, dorsal spine, and front of the chest, to be rubbed with camphorated liniment and opium, or with a stimulating liniment, with a view of modifying the spasmodic action of the respiration; and many of you have witnessed the beneficial results of this practice, at St. John's Hospital, the Free Hospital, and the Western Dispensary, in hooping cough and spasmodic croup. You have repeatedly

heard mothers requesting the liniment in preference to the antispasmodics prescribed for internal use; and these individuals have almost invariably declared that the hooping ceased, or was very much diminished, after the frictions with the liniment. When there is much spasm excited by respiration, frictions on the chest are extremely efficacious. Large doses of tartarized antimony are contra-indicated when infants suffer from gastro-enteritis. A single emetic of it, or any other irritating medicine, is in such cases injurious.

Others advise hydrocyanic acid, combined with the compound tincture of camphor, and liquor colchici, in doses suited to the age and strength of the infant. If we analyse this plan of treatment, we shall find that we influence the external respiratory nerves, while we use antiphlogistic means to abate the local inflammation.

We must always recollect that the tendency of laryngitis or trachitis in infants or adults is to spread over a part or the whole of the air-passages, to excite pulmonary congestion or pneumonia, and also cerebral congestion, which is often succeeded by effusion or hydrocephalus, and hence the antiphlogistic treatment as already described is indispensably necessary. When the patient possesses reason, and will follow advice, the vapours of ether, vinegar and water, camphor, &c. are placed near the mouth or nostrils for inhalation. Dr. Baillie very much doubted the efficacy of blood-letting in acute laryngitis of adults, and Dr. Armstrong followed it with the use of colchicum, which has a remarkable power of subduing the action of the heart, and inducing general relations. (For a most instructive lecture on this medicine by my colleague, Dr. Epps, see my Journal for 1834, vol. vi).

When all means fail, and suffocation is threatened, the operation of tracheotomy or laryngotomy is required. A new method of performing this operation was lately proposed by my friend Sir James Murray of Dublin, and that is, by making an incision on raising the integuments by pinching them, and making an elliptical opening. The next step is to raise one or two rings of the trachea with a tenaculum, and make a similar opening through them. By adopting this plan, all inconvenience caused by the flow of blood from the wounded parts will be avoided. (See Murray on Heat, and Humidity, &c. 1829; and Carmichael in Dublin Medical Journal, 1833). Mr. Hunter was the first who proposed laryngotomy or tracheotomy in croup. For a farther account of the modes of performing the operation, I must refer you to the standard works on surgery.

When the disease becomes chronic, blisters and antimonial ointments are applied to the front or back of the neck, the bowels regulated, the general health improved by the use of tonics, mercurial alteratives, &c. and the body, but especially the neck, kept

warm in cold weather, by flannel, silk, or fur, worn around it,

Ulceration of the larynx is a rare disease in infants, though occasionally met with in adults, and may end in phthisis termed laryngeal, which may and will often defy all methods of treatment except tracheotomy. (See Murray and Carmichael's cases in the works already cited).

Angina with Alteration of Secretion—Cynanche Trachealis—Diphtheritis—Trachitis—Croup.—This disease is an inflammation of the larynx and trachea, which may extend into the bronchial tubes, and be followed by the formation of an adventitious or false membrane.

The disease comes on suddenly, and is accompanied by a short dry cough, a crowing respiration like the sound made by a cock, or as of air passed through a metallic tube; the breathing speedily becomes laborious or difficult, and the infant is feverish. The causes are exposure to cold, and the attack is confined to infants and children from the age of one to thirteen years. The disease is endemic and most common in low, moist, and cold situations, and also bleak situations, as on the sea shore. It is sometimes epidemic; and was at one time supposed to be contagious. It is most frequent in winter, spring, and autumn, when the vicissitudes of the weather are most remarkable. As the disease advances, the respiration becomes difficult, the face, head, and lungs congested, speech suppressed and suffocation imminent. When the symptoms are urgent, a mucosity or layer of lymph is secreted, a false membrane forms and acquires different degrees of thickness, and sometimes filling up the larynx, trachea, and bronchiæ. The disease often terminates fatally in twenty-four or thirty-six hours, though it may assume a chronic form, and continue for five, six, or more days.

On opening the body after death, we usually find manifest signs of inflammation of the larynx, trachea, and upper part of the bronchiæ. The mucous membrane is tumefied and red, though in some cases it is of the ordinary colour, when the disorder was spasmodic; but in most cases there is an adventitious membrane lining or obstructing the whole of the inflamed parts. When the disease terminates suddenly, the adventitious membrane is usually confined to the larynx or trachea; it is either moulded into a tubular form, or appears in detached portions mixed with mucus or effused albumen. It is occasionally separated from the mucous tissue by a viscid or puriform fluid; and at other times adheres closely to the subjacent tissue. Lastly, cases have been observed in which the mucous membrane is merely covered with a viscid fluid, or with pus, and still death took place as rapidly as in those instances in which the false membranes existed (Guersent). The term *false croup* has been applied to this form of the disease.

Treatment.—The indications of treatment are to remove inflammation of the laryngo-tracheal mucous membrane, by sanguineous evacuations, both local and general, leeches, cupping, by purgation, diaphoretics, blisters, sinapisms, or those means which were recommended for the cure of ordinary laryngo-tracheal inflammation. Emetics are given in croup, and often cause the expulsion of the adventitious membrane. The warm bath, followed by leeches, blisters, or mustard fomentations to the larynx and inferior extremities; and when there is cerebral congestion, and danger of meningitis, or hydrocephalus, leeches ought to be applied behind the ears, and the rest of the treatment advised for these morbid states, employed. The false membrane is sometimes expelled by vomiting, or by the alvine dejections; but in other cases it cannot be dislodged, and causes suffocation.

When the remedies now advised are actively employed, we should exhibit calomel alone, or with an appropriate dose of antimonial or James's powder every hour, and it is seldom necessary to urge the dose to more than twenty or forty grains. Dr. Hamilton has administered nearly twenty times this quantity.

It is the opinion of M. Bretonneau and Dr. McKenzie, that the effusion of albumen commences on the soft palate and fauces, and they recommend alum in powder, or in solution, as an application to the affected part. The one may be blown into the throat, and the other applied with the top of a quill.

Mercurial frictions are highly useful, as recommended in laryngitis.

It is important to inform the young practitioner, that sloughing of the cheek and jaws may result from mercurial salivation; but this is a comparatively rare occurrence. It is, however, extremely difficult to affect children with mercury, and the cases alluded to are exceptions to the rule. When all remedies fail to arrest the disease, and when suffocation is threatened, laryngotomy or tracheotomy should be performed. M. Bretonneau states that he has removed the false membrane through the artificial opening, with a forceps; and when he could not accomplish this, on account of the fixation of it, or its descent into the trachea and bronchiæ, he proposes to pass nitrate of silver into the opening, and apply it to the membrane. Perhaps the inhalation of iodine might promote absorption, but it would be difficult to employ it in children.

The sulphate of copper has been strongly recommended by some German writers in repeated doses, but some of the cases in which it was employed were not croup.

Angina Œdematosa.—We often see infants and occasionally adults, apparently affected with angina-laryngea, trachitis or croup, who die, and on dissection present the sides of the glottis œdematous, and in close con-

tact. The symptoms are extremely obscure, and the suddenness of the disease, accompanied by extreme difficulty of respiration, are the chief signs. The disease often succeeds general anasarca, the voice is œgophonous, or resembles that of a goat.

When adults are affected they complain as if something had got into the glottis, the inspiration is difficult, the expiration easy. In some cases the disease is slight, and the patient supposes he has swallowed a fish bone, or a pin, but the real cause is the disease in question. I once attended a baker, who imagined that the cause of the disease was a piece of wood which he swallowed; and women generally think they have swallowed a pin. The effects of œdema are pulmonary and cerebral congestion.

Treatment.—The remedies for laryngitis, trachitis, or croup, are to be employed for the removal of this disease. If these fail—and this is the usual result—laryngotomy is to be immediately performed in the manner recommended by Sir James Murray, which will scarcely require a tube, which is a certain source of irritation. Counter-irritation, by means of blisters, antimonial ointment, issues and setons in the neck, are also useful, and materially contribute to a cure. I need scarcely state that purgation and attention to the general health are necessary.

According to my experience, œdema of the glottis in infants or adults generally proves fatal, though I have often known exceptions in cases of adults.

There is another disorder which is referable to the glottis, larynx, and trachea, or wind-pipe, which demands our serious consideration before we describe the diseases of the bronchiæ or chest, and that is spasmodic croup, or asthma of infants.

Spasmodic Croup, or Asthma of Infants.—This is termed “a peculiar species of convulsion in infants,” by Dr. John Clarke; and is also described by Dr. Cheyne in his work on Hydrocephalus. The disorder consists in crowing inspiration, with purple complexion, not followed by cough; the muscles are rigid, the thumbs are clenched on the palm of the hand, the extremities are œdematous, livid and swollen, and general convulsions supervene. It has proved fatal in several cases.

The disorder has frequently occurred during sleep, the respiration becomes laborious or difficult, the face is purplish, and death is caused by asphyxia. One of the best accounts of this affection has been lately given by Dr. Marsh, of Dublin. He has termed it, “A peculiar convulsive disease affecting young children, which may be termed spasm of the glottis.” This affection was called spasmodic asthma of infants by Miller and Parr.

Treatment.—The same treatment as in laryngitis, trachitis, and croup is advisable. Dr. Marsh ascribes the disease to irritation or congestion, at the origin of the pneumo-

gastric or eighth pair of nerves. It is caused by an affection of the muscles, and the treatment consists in improving the general health.

Dr. Marsh contends the disorder is purely spasmodic. Anodyne or stimulating liniments applied to the face, cervical and dorsal spine, as in whooping-cough—in general afford relief. During the paroxysm, bleeding, leeching, warm bathing, and purgation, are necessary. Change of air and diet are strongly recommended.

—o—

Some Account of the Bronchocele or Goitre of Nipal, and the Cis-and Trans-Himalayan Regions. By Mr. M. J. BRAMLEY.

No disease, perhaps, is so extensively distributed over the mountainous countries of Asia as Bronchocele; for it extends from the frontiers of Assam, (27 degs. N. L. 91 degs. E. L.) through Bijnee, Cooch, Bahar, Rungpore, Dinayepore, Purnea, Tirhoot, and Betiah, along the northern boundary of Oude in Gorruckpore, Barraitch, Piliebeat, on the confines of Rohilkund to Hurdewar, (30 degs. N. L. 78 degs. 25 E. L.) at Yarkund, in the tract between the great wall and Zehol, in the Tibetan and the Mongolian districts, and in those round Lake Baikal, and in that of Kirensk on the Lena.

The valley of Nipal or Nepaul is an extensive tract in 27 degs. N. L., elevated at least 4500 feet above the level of the sea, lying at the southern base of the eastern division of the Himalaya range, between that and the kingdom of Oude, with a diameter of about 16 miles.

Though broken into numberless irregularities, its surface is most extensively cultivated. It possesses three cities. Kathmandu, Bhatgang, and Patan, and 226 towns and villages. The number of houses in the valley is calculated, according to a recent census, at 41,798, of which the cities contain 21,116, in the following ratios, Kathmandu, 10,767; Bhatgang, 4700; and Patan, 5659. The population of the valley deduced from these data, and allowing seven souls to each house, would amount to 229,586, which is believed to be below the real number.

Though bronchocele is frequent among the whole of this population, it is in certain towns and districts more prevalent than in others. The lowest rate among the inhabitants of the cities was $3\frac{1}{4}$ per cent. for Kathmandu, and 4 per cent. for Bhatgang and Patan. According to calculations made of twelve of the small towns and villages, the average proportion of the disease was rather under 11 per cent.—which, from subsequent inquiries, Mr. Bramley is led to regard as representing the average proportion of the disease among the whole population,

In some villages in the neighbouring mountains, and on the borders of the valley, elevated from 500 to 2000 feet above the level of the valley, the disease is still more prevalent. At Phirphen and Mata Pirtha it was at the rate of 15, at Chitlong 40 per cent.; and at a small village named Carphu, situate on the crest of a mountain, of 53 inhabitants, 48 were affected with the disease, giving a prevalence equivalent to 90 per cent. These facts, combined with the statement, that the author has witnessed the disease in families who habitually reside on or near the summits of mountains not less than 7000 feet above the level of the sea, he employs to disprove the inferences drawn by Saussure, Foderé, and Georget, that the disease is peculiar to the lower valleys, and disappears as we ascend.

It is to be observed, on the other hand, that in certain localities the disease is almost unknown, though it may be extremely prevalent in the neighbourhood. Thus in the town of Sanchu, situate on an eminence, and surrounded by a luxuriant forest, which rises from a range of hills, by which it is bounded before and laterally, among a population of 3000, 600 persons were examined without presenting a trace of the disease, and Mr. Bramley was informed that not above twelve persons were affected with it. At Loovhu also, a town situate on an open plain, and surrounded by cultivated grain fields, not more than 2 per cent. of the inhabitants were affected.

In India, the endemic prevalence of bronchocele first begins to betray itself in Hindostan. It appears on the left bank of the great Gundük river among the inhabitants of the villages, sometimes very generally, in other instances very scantily. In proportion as the traveller approaches the foot of the Nipal mountains, the disease becomes more frequent; and in this district it is calculated by Captain Turner, that it affects one sixth of the whole population, and in the tract denominated the Terria or Terriani, especially adjoining to the great forest (Bhabar), scarcely an individual is exempt from the disorder. Some idea of the extent to which it prevails may be formed by the following tabular statement of the number of the population of three villages in the neighbourhood of Betiah, 50 miles from the foot of the hills.

<i>Names of the villages.</i>	<i>No. of inhabitants.</i>	<i>No. with Goitre.</i>	<i>No. without Goitre.</i>
Chouby	234	65	169
Maha-deo	236	103	133
Lal-Serai	177	65	112
	647	233	414

Thus in a population of 647 persons, more than one third were bronchoceleic; and it may be added, that in the first two villages, 14 children under ten years of age, and in the third village, 2 children under that age

were affected. Even the lower animals are often found with bronchocelic enlargements.

As to its comparative prevalence among the two sexes, the reports of the towns of Handigang and Deopatan may be conveniently employed.

Report of the Town of Handigang.

	Witht. Goitre.	With Goitre.	Total counted.
Men	325	29	354
Women	340	31	371
Boys	169	3	172
Girls	145	2	147
	979	65	1044

Males to Females, 32 to 33. Per centage on whole 6 $\frac{1}{2}$.

Report of the Town of Deopatan.

Inhabitants.	Witht. Goitre.	With Goitre.	Total counted.
Men	474	34	508
Women	411	38	449
Boys	218	5	223
Girls	296	6	275
	1372	83	1455

Males to Females, 39 to 41. Per centage on whole 5 $\frac{1}{2}$.

It thence results that in the town of Handigang, the proportion of bronchocele women to men is 33 to 32, and in that of Deopatan 41 to 39, showing a slight preponderance in the number of bronchocelic females. It is to be farther observed, that in men the affection is often partial, and so inconsiderable as to escape general or cursory observation, yet that when inspected, it often turns out that individuals who say they have no *goitre*, are found to present palpable though slight enlargement of the thyroid gland.

No period of life is exempt from its attacks; and both children and the lower animals may come into the world with *goitre* in Nipal. During the residence of Mr. Bramley, a kid was born with a *goitre* as large as its head; and not only lambs are born bronchocelic, but puppies bred from English dogs become bronchocelic at a month old.

As to the rate at which it respectively affects children and adults, of 124 bronchocelic males, fifteen were boys under ten years of age, six of these were under six years of age. Of 140 bronchocelic females, fifteen were under ten years, and of these three were under four. In these children the tumours were large enough to attract observation. The statement made by authors, that the age of adolescence is the most favourable period for the development of bronchocele is in general terms confirmed by the observation of Mr. Bramley.

The author distinguishes the tumour, like the generality of writers, into three kinds. 1st, the cellular or cystiform, consisting of an aggregation of cysts; 2d, the vascular or pulsating; and 3d, the lymphatic or glandular.

On the subject of the *causes* of bronchocele, we find an inquiry into the influence of the water of the countries in which it is prevalent, the diet of the inhabitants, the mode of living, the atmospheric changes, and meteorological vicissitudes.

From chemical examination of seven specimens of Nipal water by Mr. Prinsep, it appears that these contain no ingredients, saline or earthy, in sufficient quantity to account for the origin of such a disease.

Mr. Bramley then enters into a sufficiently detailed view of the usual diet of the different Nipalese, Himalayan, and Tibetan tribes, and arrives at the general conclusion, that there is no ground to attribute the prevalence of bronchocele to any particular species of diet.

From a similar review of the atmospheric and meteorological characters of the climate of Nipal and the Himalayan regions, it appears to be equally difficult to discover any connexion between the prevalence of bronchocele and the nature of the climate. The climate of Nipal, indeed, as that of the sub-Himalayan districts, seems to be very similar to that of the mild or colder European countries, with this exception, that in the lower regions it is rather warm, while in the upper it may be absolutely cold, so that a few hours' walk may often conduct the traveller from tropical heat to intense cold. The only district positively injurious to the functions of the animal frame, and unfavourable to human life, is that of Teriani, already mentioned as contiguous to the great forest called *Bhabher*; and here the soil and atmosphere are merely miasmatic, or what is now denominated malarial, that is to say, productive of ague and jungle fever, and all their accompaniments; and in those in whom it does not produce miasmatic fever, it betrays its deleterious influence, like that of the Sologne and the maritime Alps in France, or the Maremma in Italy, in stinting the growth of the body, or inducing a species of deranged action of the digestive organs, and the abdominal circulation, and a consequent hypotrophy of the whole frame. Here, indeed, bronchocele is extremely prevalent; but, while the disease is not in the same degree prevalent in districts which are equally miasmatic, it is very abundant in situations where no very decided proof of miasmatic air exists.

In short, while Mr. Bramley admits that the etiology of bronchocele is involved in inexplicable difficulties, that no satisfactory theory has been yet proposed, and, above all, that its prevalence under every species and variety of climate shows that it is peculiar to none, he suggests the following general circumstances as concurrently likely to produce the disease.

In the *first* place, since the higher classes are less liable than the inferior, the inhabitants of the towns less generally attacked

than those of the country, or, in other words those who, in the pursuit of their daily duties, are less exposed to the weather than those who are most, are least liable to the disease—he infers that a powerful exciting cause is the frequent or habitual exposure of the neck especially to the vicissitudes of the weather. The natives of the east always have the neck uncovered; and though this practice be not only not injurious, but requisite in the less elevated and warmer countries on the coasts of India, it may become capable of inducing glandular enlargement in the more elevated regions, where the atmospheric temperature is not only lower, but where, from the vicinity of mountain ridges, currents of cold air must be and are of frequent occurrence.

Secondly, notwithstanding this evidence of the general influence of the atmosphere in Nipal, in inducing bronchocele, Mr. Bramley infers that there is in the territory of Nipal and similar places, something in the locality capable of exciting the disease into action. Thus foreigners who come thither to reside, as the Sepaihees (*vuigo* Sepoys) and servants of the Residency, may be, and are, occasionally attacked; and the most prompt method of arresting the progress of the disorder thus induced, is to remove immediately from the locality.

In the third place, bronchocele, Mr. Bramley reminds his readers, is always more prevalent in mountainous districts or their neighbourhood than elsewhere.

Though we give these arguments arranged according to the mode nearly in which they are given by the author, we must nevertheless express our doubt whether all of them be not referable to the same head, of exposure of the neck in a climate liable to extreme vicissitudes, and violent currents of cold wind in persons otherwise accustomed to considerable external warmth. Even this view, however, is embarrassed with difficulties; and it does not enable us to understand why brute animals should become bronchocele.

In conducting the treatment of this epidemic malady, Mr. Bramley proceeded much upon the principle of its being a local disorder, and little dependent on constitutional ailment.

With this view he began first by ordering the application of a bandage or neckcloth over the tumour, upon the twofold principle of protecting the gland from atmospheric vicissitudes, and the injurious impressions of the cold air, and applying pressure so as either to prevent further increase, or excite absorption, and give a uniform support. The next measure was the employment of simple friction; and under the two means now specified several cases appear to have been cured. In the class of cases which resisted, or seemed to resist the influence of these measures, the internal use and the local application of iodine were employed.

For the former purpose the tincture was exhibited in the usual dose; and for the latter, the iodine ointment was diligently rubbed over the tumour.

The result of this mode of treatment was the following. Of 116 cases, the total number treated, including several of the Sepaihees, 57 were discharged cured so completely, as to leave no trace of the existence of the tumour. Fourteen, in whom the disease had nearly disappeared, absented themselves. Thirty-four derived considerable benefit from the use of the remedies, and would in all probability have been cured, or nearly cured, had they been regularly in attendance, and persevered in the use of the measures. In six only partial relief was obtained after a trial of two months; and in five cases chiefly middle-aged persons, in whom the disease was of long duration, perhaps with morbid change of structure, the tumours remained entirely unchanged.—*Edinburgh Med. and Surg. Journal.*

Contributions to the Pathology of the Nervous System. By E. GEDDINGS, M.D., Professor of Anatomy and Physiology in the University of Maryland.

CASE I.—*Apoplexy—Recovery—Death by a second attack five years afterwards.*

AN aged black woman, about five years previous to her death, was attacked with hemiplegia of the right side, from which she partially recovered in the course of some months. Considerable impairment of the powers of sensation and motion nevertheless remained. She continued to drag her right foot when she walked; her powers of speech were considerably impaired; and when spoken to, her countenance always portrayed the vacant stare and expression of idiocy. No farther particulars of her case could be obtained.

On the 16th of July, 1827, she appeared well as usual, and had in the morning carried one or more buckets of water on her head. In the course of the day, however, without any symptoms premonitory of such an attack, she fell down in a fit of apoplexy, and immediately expired. I was requested by my late friend, Dr. Isaac Wilson, to examine the body, which was done about six o'clock of the same evening, in presence of him, and my friend, Dr. E. Horlbeck. The body was still warm, but presented nothing of interest externally. The cranium was preternaturally thickened, and at some points so much so, as to be with difficulty broken through with the hatchet. The dura mater adhered intimately with the bone, and when separated, its external surface presented a number of small whitish-coloured points, some of them as large as a barley corn, which seemed to consist of organized coagulable lymph, very much consolidated.

Posteriorly, this membrane had its natural thickness and consistence; but that portion which covers the anterior lobes of the brain, was considerably attenuated. The arachnoid was studded over with the same species of organized adventitious points, which were observed on the external surface of the dura mater. The posterior lobes of the cerebrum were of their natural volume and configuration, but the anterior were so much atrophied, as not to present more than one half their natural size. On insinuating my finger between the orbitar plates of the frontal bone and the corresponding portion of the organ, the inferior face of the left anterior lobe was slightly lacerated, and a coagulum of blood, as large as a pullet's egg, escaped. On cutting into the left hemisphere, a large cavity was discovered extending through the whole central point of the hemisphere, and communicating with the corresponding ventricle, which contained several small clots, and a considerable quantity of fluid blood. The walls of the cavity were spongy and flocculent throughout a great part of their extent, and these flocculi were highly vascular. About the centre of the middle lobe was a large cyst, formed by a strong membrane, smooth and uniform upon its internal surface, and which had probably formed around the extravasation which took place at the period of the attack of hemiplegia. The cyst was large enough to contain a common sized hen's egg, and was of a yellowish colour. The portion of the brain which corresponded to its lower surface was of a dark brown colour, and was of an uneven, indurated, fibrous character. The part thus affected was about an inch in breadth, by two or two and a half inches in length. Situated deeply in one of the infarctuosities of the middle lobe of the brain, there was a second cyst of similar dimensions, but possessing all the characters of the one described. The corpus callosum was entirely destroyed on the left side, and the corpus striatum presented a highly vascular flocculent surface. The disorganization extended for some distance into the left crus cerebri. The larger cyst reposed in contact with the middle cerebral artery, which had been ruptured in the original attack, and which now presented a few small points of ossification. The substance of the right hemisphere was considerably indurated, as were also the pons varolii, medulla oblongata, and cerebellum. The floor of the right ventricle, to the extent of one inch and a half, had its lining membrane destroyed, and the adjacent structure seemed to be in a state of ulceration.

This case is interesting, as shewing satisfactorily the steps adopted by nature, in repairing the injury inflicted upon the brain by an extravasation of blood within its substance, and conducting the case to a favourable issue. Reflecting upon the post mortem appearances, and the previous history

of the individual, it is manifest, that at the time at which she became affected with hemiplegia, an extravasation of blood took place in the left hemisphere of the cerebrum. The injury arising from this cause had, however, been in a great measure repaired, or at least counteracted, by the development of a cyst surrounding the coagulum, the effect of which was, to isolate it from that organ, and thus obviate the serious consequences which otherwise would have ensued. The ulcerative process, however, which was excited by the original disease, continued gradually to inflict its ravages upon the adjacent structures, up to the period of the last fatal attack, when in consequence of a considerable artery being opened, either by ulceration, or a rupture of its parietes, they having in the mean time become exceedingly fragile, a sudden extravasation took place in the excavation, and death was the consequence.

Nor is the case without interest in a psychological point of view. The co-existence of extreme atrophy of the anterior lobes of the brain, which, according to the tenets of phrenology, are the seat of the intellectual faculties, and the idiotic character of the individual, speak forcibly in favour of their existence in the relation of cause and effect, and furnish an additional fact, or at least argument, in favour of the correctness of the principles of that doctrine.

CASE II.—*Apoplexy—Death in a few hours after the attack.*

Captain D., aged about 45 or 50, had been for some time affected with ascites, for which he had been successfully treated by my friends, Doctors Samuel and Wm. N. Baker. After partaking of a hearty breakfast, he was attacked suddenly, on board of his vessel, with a fit of apoplexy, in which he was seen by Dr. Wm. N. Baker, who bled him freely, and had him conveyed to the Baltimore Infirmary, where he united with me in the treatment of the case. At the period of his admission, he was in a state of profound insensibility; his respiration laborious and stertorous; his pupils contracted; the skin somewhat hot, and of nearly an equable temperature throughout; his pulse somewhat full and hard, and his tongue drawn to the left side. In this condition we deemed it advisable to abstract more blood, and the temporal artery was accordingly opened in front of the ear, and while the blood was flowing from it, the vein in the arm was again opened and allowed to bleed. With a view of assisting these means, and creating revulsion, ice was applied to the head, and sinapisms to the feet and legs. A stimulating cathartic enema was thrown into the bowels, but as it was immediately returned without effect, it was repeated with no better success by means of O'Biern's rectum tube, which was passed up to a sufficient extent to ensure

projection of the enema into the sigmoid flexure of the colon. As it was suggested that the stomach was probably still distended with the ingesta which had been taken in the morning, and as the individual was incapable of swallowing, we determined to convey a strong solution of sulphate of zinc into the stomach, by means of the stomach tube, passed down the œsophagus, with a common syringe attached. No effect following, a quantity of a saturated solution of common salt was afterwards thrown into the stomach by the same process. But that organ could not be made to respond.

All the means resorted to for the relief of the patient proving ineffectual, he expired few hours after his admission.

On proceeding to the examination of the body, we first directed our attention to the head. When the cranium was opened, the membranes were found considerably injected, and a thin stratum of coagulated blood was found reposing upon the surface of the left hemisphere, immediately beneath its arachnoid covering. The lateral ventricles contained a large quantity of fluid blood mingled with serum. In the plexus choroides of both sides, there were a number of small transparent cysts, some of them as large as a pea. The fourth ventricle was also filled by a fluid of the same character as that which occupied the lateral ventricles—and along the right side of the medulla oblongata, entangled in the radicles of the hypoglossal, pneumogastric, and facial nerves, there was a considerable extravasation of dark coagulated blood. The brain, in other respects, presented nothing remarkable, except that its vessels were somewhat more injected than natural.

On opening the abdomen, which was somewhat prominent, the cause of the dropsy under which the patient had previously laboured, was found to have been a diseased state of the liver. This organ was enlarged to nearly twice its natural dimensions, and was in the condition to which the term *sclerosis* or *scleroma* has been applied. The enlargement and induration was owing in part to hypertrophy of its granules, but chiefly to a similar condition of their interstitial cellular tissue.

In addition to other features of interest presented by this case, not the least is that which has reference to the situation of the extravasation upon the radicles of the nerves of the tongue, lungs, and the stomach. Hence we find, that the tongue was partially paralyzed and drawn to the left side, in consequence of the injury sustained by the nerve which controls the antagonist muscles—that the respiration was embarrassed and stertorous from a similar implication of the radicles of the pneumo-gastric nerve; and finally, that the contractions of the stomach could not be roused, in consequence of the influence of that nerve having been suspended. The extravasation upon the

surface of the brain, as well as that within the ventricles, must likewise have contributed much to the development of the symptoms presented by the patient, but their influence cannot be so directly traced, or so accurately estimated.

CASE III.—*Apoplexy—Sudden Death—Extravasation upon the whole surface of the Brain.*

I was requested by my friend, Dr. Lining, to examine the body of his man servant, who had died suddenly and unexpectedly. His habits had been intemperate, but he had enjoyed good health. On the day preceding his death, he had complained of slight indisposition, for which a cathartic was administered. In a few hours he was found dead.

On opening the cranium, and slitting up the dura mater, the whole of the external surface of the brain was found completely incased in a solid coagulum of blood of considerable thickness, the convolutions being only apparent through it at their most elevated points. The extravasation was most abundant at the base of the organ, where some of the blood was still in a fluid condition. The substance of the brain was healthy, and no other lesion of importance was discovered.

In this case, the extravasation seems to have taken place in consequence of an intense hemorrhagic action of the vessels of the pia mater, as most of the blood was situated beneath the arachnoid membrane, and in the inflexures of the convolutions. No extravasation whatever existed, either within the ventricles or the substance of the organ. Nor could we by the most careful examination, discover a rupture of any of the larger vessels which distribute blood to the brain. Indeed, as the individual was young, and in the prime of life, the arteries still retained their natural elasticity, and had not yet acquired that fragility of tissue, which results from a slow transformation and degeneration of their tunics, and which so often lays the foundation for apoplexy in the more aged. As he had been labouring under a feverish disposition, which may have predisposed the encephalic organs more or less to take on disease, it is probable, from his habits of intemperance, that the hemorrhagic action, and his final death, may have been induced by immoderate alcoholic potations, taken while his system was in a state of preternatural excitement.

CASE IV.—*Apoplexy from Excessive Repletion of the Stomach—Sudden Death—Large Extravasation in the Vicinity of the Fissure of Sylvius.*

A coloured woman, aged about 50, somewhat corpulent, and the mother of several children, after a hearty meal of animal food, peas and rice, tumbled down in a state of insensibility, and immediately expired. I was requested by a medical friend, who

had been called to see the case, to make a post mortem examination. As soon as the cranium was opened, a considerable collection of blood was discovered about the base of the brain, much of which was still in a fluid condition. When the organ was removed from its cavity, a large coagulum was found occupying the fissure of Sylvius, and extending for some distance into the corpus striatum. There was likewise considerable extravasation within the corresponding lateral ventricle. The arteries of the brain were rigid, much dilated, and studded over with numerous points of ossification. The extravasation had taken place in consequence of a rupture of their tunics.

We next proceeded to examine the stomach; and here we had fully revealed the source of the mischief inflicted upon the brain. This organ was impacted with peas, rice, homminy, and other articles of the individual's repast, to a degree to which it would scarcely be possible to believe could be borne without extreme suffering, and an extensive embarrassment of the functions of the whole of the associated organs. Its condition was such as to encroach upon the intestines, compress the aorta, and the vessels given off by it in the epigastric region, press upon the plexus of nerves behind the stomach, and finally force up the diaphragm upon the lungs, so as to interrupt their play, and thus embarrass the function of respiration, thereby interrupting the passage of the blood through them, and consequently impeding its return from the head. Being thus confined on the one hand to the vessels of the brain, by these causes, and driven upon it, on the other, by the pressure sustained by the aorta, which prevented the distribution of the usual quantity of blood to the lower part of the body, it is not to be wondered, when the fragile state of the tunics of the cerebral arteries is considered, that they should have been unable to sustain the onus suddenly thrown upon them, and that they gave way under its influence. —*North American Archives of Med. and Surg. Science*, Nov. 1834.

Reviews.

A Practical Treatise on Diseases of the Teeth, in which the Origin and Nature of Decay are explained, with the Means of Prevention pointed out. By William Robertson, Esq. Surgeon.

(Continued from page 248.)

WE resume our review of this work, as the author professes to explain the cause of caries of the teeth, or toothach. He first

describes the theories of Hunter, Fox, Bell, and others, who ascribed it to inflammation or gangrene. He urges the following arguments against this conclusion, and they seem to be satisfactory.

"Now there is one simple, and, I think conclusive argument, both against the theory of Mr. Bell, who refers the origin of decay in the teeth to inflammation in their bony structure, and to that of Mr. Fox, who refers it to inflammation of their internal membrane; namely, that as all teeth are furnished with a similar lining membrane, and all are possessed of the same bony structure, they should all (according to these views) be equally subject to the same disease, and no one class of teeth should therefore be more frequently the seat of caries than another; and yet it is a fact universally admitted, and acknowledged by the authors just quoted, that this is not the case.

"Mr. Fox says 'the molares (or large grinding teeth) are more subject to this disease than any other teeth; and that the incisors of the upper jaw are very frequently affected by it, whilst the incisors of the lower jaw very seldom become decayed.'

"Mr. Bell says, 'The teeth most liable to mortification are undoubtedly the dentes sapientiæ; the first molares are also frequently decayed at an early age; so much so that it is often necessary to remove those teeth in consequence of severe suffering from toothach, even before many others of the permanent set are perfected. The cuspidati, both superior and inferior, are comparatively seldom the subjects of disease; and the inferior incisors still more rarely.'

"Mr. Fox has attempted no explanation of these facts, and Mr. Bell has only endeavoured to account for the greater liability to decay in the dentes sapientiæ, or wisdom teeth.

"This probably arises,' he remarks, 'from their being formed at a later period of life than the other teeth, when the constitution is doubtless in a less favourable state for the production of newly formed parts, than during early infancy, when the process of new formation is going on with rapidity in every part of the system.'

"The statement of Mr. Bell, as to the greater liability to decay in the dentes sapientiæ, is perfectly in unison with my own experience; but his attempt to explain it is not satisfactory, and it appears to be inconsistent with other statements made by him. If this liability depended, as Mr. Bell suggests, on their being formed at a later period of life than the other teeth, why should the molar teeth, which are formed in early infancy, and at the period which, according to him, is most favourable to the process of new formation, be so peculiarly disposed to decay? Mr. Bell himself, in describing the various predispositions of the

teeth to caries, has placed the molar teeth next in order to the dentes sapientiae, and Mr. Fox has declared them more subject to this affection than any of the other teeth.

"The same objection which has been made to the proximate cause of decay, as depending on inflammation of the bone, or internal membrane of the tooth, is equally applicable to the supposed exciting causes of the disease; such for instance as hot and cold climates, the taking of food at a high or low degree of temperature, the drinking of strong spiritous and fermented liquors, a disordered state of the stomach, a debilitated constitution, &c. If decay in the teeth were occasioned by any of the above-mentioned causes, all being equally exposed to their operation, they would in like manner be equally the subjects of disease."

We entirely agree with our author that if the alleged causes of caries supposed by the preceding writers were real, there could be no scientific reason why one set of teeth should be more liable to decay than another. Every one knows that the different classes of teeth are liable in different degrees to caries, and our author proposes to explain the cause of caries, by referring it to the external form, configuration, and juxtaposition of the different classes of the teeth. He thus proceeds:—

"This principle I shall now proceed to establish, by passing successively under review the several divisions of the teeth in the order of their liability to decay; and consequently the first that claim our attention are the molares, including the dentes sapientiae, which, from the circumstance of their appearing at a period of life subsequent to the formation of all the other teeth, are frequently considered as a separate class, yet they undoubtedly belong, as shown by their structure, to the molar division of the teeth.

"It has before been admitted that these are more subject to decay than even the molar teeth, but the aptitude arises from a different cause, which will be afterwards explained; for the present I shall include them with the molar teeth, because they are similarly constructed, and on that account are equally liable to decay.

"The molar teeth are much larger than any of the other teeth, their grinding surfaces are broad, and present an irregular cavity bounded by an elevated and uneven ridge. This surface is often intersected with numerous smaller projections or ridges running transversely and in various directions, and corresponding with an equal number of depressions, which constitute so many smaller cavities or deep pits; occasionally a fissure extends across the ridge of the masticating surface, and forms a cavity

in the side of the tooth; in other cases the masticating surface presents three or four prominences around a deep pit in the centre. These indentations are in size, depth, and number infinitely variable, so much so that we rarely meet with two molar teeth exactly alike, with the exception of the corresponding teeth of the same jaw, in which we always find a great similarity of structure.

"The liability to caries in the class of teeth now under our notice (which, as before asserted, are of all the teeth most frequently affected with this disease) will be found exactly to coincide with the irregularity of their surfaces as just described, and particularly with the depth of their indentations. Accordingly the masticating surfaces in which the deepest depressions are met with, are in the great majority of cases the seat of decay, and the first to be affected with it; and the part of these surfaces in which the disease is always found to originate, is the bottom of one or more of the deepest indentations.

"The next class of teeth most liable to decay are the bicuspidates of the upper jaw; their grinding surfaces are much smaller than those of the molar teeth; and consist of an anterior and posterior eminence, with an intermediate chasm open to its extremities, and not, as in the case of the molares, shut in by lateral prominences, thereby producing a hollow cavity or pit; these teeth are not subject to decay in the situation above described, except in occasional instances where these fissures are found to be deep and irregular. On the other hand the bicuspid is principally, and perhaps more than any other, affected with caries on its sides, which from the thickest part of the crown downwards become suddenly flat and contracted, so as to form a neck or groove immediately below that point where it comes in apposition with the contiguous tooth. In this situation we find the disease to commence.

"The next in order of liability to the disease are the incisors of the upper jaw. The surfaces of these teeth are broad, the anterior being smooth and convex, the posterior, on the contrary, being rather uneven and concave; the broadest parts of these teeth are their cutting edges, where they are placed in apposition with each other; from this part, which is thin and smooth, they gradually increase in thickness towards their fangs, so as to represent the form of a wedge; from the same point and in the same direction they diminish still more considerably in width, so that their roots diverge from each other and thereby leave interstices or openings, between them. Decay is never found upon the cutting edges of the incisors, nor is it found upon their plain convex surfaces, excepting where there is some defect in the formation of the enamel, and on their posterior surfaces, we only meet

with it when they are deeply indented, which is rarely the case. The situation where decay takes place in these teeth is at their sides immediately above the points where they unite with each other.

"The incisores of the lower jaw are less subject to decay than any of the other teeth. They are more regular and uniform in their shape, and their fangs are thicker in proportion to their bodies than those of the upper jaw, consequently, they do not present necks and interstices of the same kind. For the same reason the remaining class, the cuspidati, or canine teeth, are comparatively little subject to decay, particularly those of the lower jaw; but there is another reason why the incisors and canine teeth of the lower jaw are less subject to decay than any other teeth, which we shall hereafter point out.

"The next thing to be considered, and the only thing left unnoticed relating to the structure or position of the teeth, as far as this inquiry is concerned, is a peculiarity connected with the *dentes sapientiae* or wisdom teeth, the consideration of which was before purposely deferred. It has been admitted that they are more liable to decay than any of the other teeth, and this liability arises not only from their indented surfaces, which have been before described with the molar teeth, but also from another cause peculiar to themselves. These teeth come at a later period of life than the others; they rarely begin to appear before the age of eighteen or twenty, and often much later than that, whereas the other teeth (comprising twenty-eight in number) are completed, and have taken up their stations at the early age of ten or twelve years, and generally fill up the whole extent of the jaw, so as to leave but little space for the *dentes sapientiae*; the consequence of which is, that when these are prepared to emerge through the gum, their progress is slow on account of their confined situation; when the one half of the surface of the tooth has made its appearance through the gum, the other half continues for a considerable period of time covered, thus forming a recess between the concave and pitted surface of the tooth and the overlapping gum. It is in this situation that decay, which is so frequent in these teeth, is found to commence, and in many instances to have made considerable progress before the whole surface of the tooth has risen above the gum.

"From the review we have just taken of decay in the different classes of the teeth, it will be perceived that in regard to situation, it takes place on the surfaces of the teeth, in excavations formed between them and the projecting gum, in cavities, indentations, and irregularities on the external substance of the tooth itself, and that it occurs at their sides, in their necks, and spaces produced by their formation and relative position; in regard to frequency, that it is in proportion

to the depth of the superficial depressions, and the degree and nature of the lateral projections and interstices.

"This being the case, and decay never being found to take place upon the plain and smooth surface of the tooth, it cannot for a moment be doubted, that the predisposition to caries depends, as I have already proposed to prove, upon the external configuration or conformation of the teeth. It must be equally evident from the partial nature of the disease, and from the insufficiency of all general causes, as before pointed out, to explain this circumstance, that the existing cause of caries must be one whose operation is partial, and which has a peculiar action upon those parts of the teeth which are by their structure predisposed to the disease. The only cause capable of explaining the partial operation and the particular situations of decay, is the corrosive or chemical action of the solid particles of the food which have been retained and undergone a process of putrefaction, or fermentation in the several parts of the teeth best adapted for their reception."

He next applies his explanation to the decay of teeth in pairs, the rare occurrence of caries after the age of fifty, as compared with its frequency in early life, and to the great susceptibility to caries in the teeth of certain families. He commences by stating Mr. Hunter's views, which are of course entitled to recitation.

"In reference to the first of these facts, Mr. Hunter says, 'decay of the teeth does not seem to be so entirely the effect of accident as might be imagined; for it sometimes takes place in them by pairs, in which case we may suppose it owing to an original cause, coming into action at its stated time; the corresponding teeth being in pairs, with respect to the disease, as well as to situation, shape, &c.'

"This opinion,' he states, 'is somewhat strengthened by the fore-teeth in the lower jaw not being so subject to decay as those in the upper, although equally liable to all accidents arising from external influence, which could produce the disease in general. The fore teeth in the lower jaw appear to be less subject to this disease than any of the others; the fore teeth in the upper jaw, and the grinders in both, are of course more frequently affected.'

"It is truly extraordinary that Mr. Hunter, whose attention, as shewn by the passage just quoted, was so particularly drawn to the correspondence in shape and situation of the pairs of teeth which so frequently decay together, should not have immediately perceived that the correspondence of decay was the necessary result of the coincidence of formation. If this had occurred to his mind (and with such strong evidence before

him, it is wonderful that it escaped his penetration), he would not have had recourse to the vague and unsatisfactory supposition of some unknown original cause coming into action at its stated time; but would have seen that the corresponding teeth have the same aptitude for retaining particles of food; that the parts of the teeth where decay has its seat are the deep indentations or angles where the food is deposited; that the disease takes place in both these teeth in precisely the same situations, and that consequently they are similarly liable to decay, because they are similarly constructed.

"The oversight of Mr. Hunter is perhaps the more astonishing, as he was inclined to suspect that, during life, there is some operation going on which produces a change in the diseased part. 'The most common disease,' says he, 'to which the teeth are exposed, is such a decay as would appear to deserve the name of mortification. But there is something more; for the simple death of the part would produce but little effect, as we find that teeth are not subject to putrefaction after death; and therefore I am apt to suspect that, during life, there is some operation going on, which produces a change in the diseased part. It almost always begins externally in a small part of the body of the tooth.'

"We have seen that Mr. Hunter has left the cause of the liability of the teeth to decay in pairs undefined; and the only explanation suggested by Mr. Fox, which is altogether gratuitous and far from satisfactory, is 'that they acquire this disposition to decay from some want of healthy action during their formation.' Mr. Bell explains this fact on the same principle as Mr. Fox, which principle we have before seen him apply with so little success to explain the frequency of decay in the *dentes sapientie*.

"The next fact to be noticed is the rare occurrence of decay in the teeth after the age of fifty, as compared with its frequency in the early periods of life. 'This disease, and its consequences,' says Mr. Hunter, 'seem to be peculiar to youth and middle age; the shedding teeth are as subject to it, if not more so, than those intended to last through life; and we seldom or never see a person whose teeth begin to rot after the age of fifty years. This might be supposed to arise from the disproportion that the number of teeth after fifty bear to them before it; but the number of diseased teeth after fifty do not bear the same proportion.' This statement is also in accordance with my own experience; and although it has not been accounted for by Mr. Hunter, or the other writers on this subject, it can readily be explained on the principle insisted upon in this treatise.

"It has before been shewn that the grinding teeth are most liable to caries in consequence of their deeply-indented surfaces. In

early life, when the teeth appear through the gums, the prominences upon their grinding surfaces are higher, and their depressions consequently deeper, than at a more advanced period; and should the formation of these indentations be calculated to retain particles of food, the operation of decay would immediately commence, and the loss of these teeth in early life would be the result. On the other hand, it may be safely presumed that the surfaces of such teeth as remain sound to the advanced period alluded to by Mr. Hunter, never were deeply indented, or they would not have escaped decay; but having escaped it, they are, in every succeeding stage of life, less and less disposed to the effects of this disease; for we generally find that, at the age of fifty, the surfaces of the teeth are worn down, and become smooth from a long course of mastication, consequently the cause of liability to decay in this situation (which of all others is the most liable in youth) is entirely removed; and when decay does occur, it is principally confined to the sides of the teeth, and is occasioned by a lodgement of food in the interstices produced by a receding of the gums.

"If the doctrine insisted upon by Mr. Bell were correct, the teeth would be more liable to decay at the advanced age above alluded to than during the earlier stages; for at this period a filling up of bone has taken place within the tooth, thereby lessening the internal cavity, and increasing the distance between the external surface of the bone and the centre of circulation. But, as this is not the case, Mr. Bell's notions regarding the primary cause of decay must be fallacious; and moreover, we constantly find decay to commence in the depressions and irregularities of the teeth in situations nearest to, and not the most remote from, the centre of circulation.

"The next fact under this head to be explained, is the great susceptibility to caries in the teeth of particular families; and it is a remarkable circumstance that there is no feature in which the different members of a family bear so striking a resemblance to each other as in the formation of the teeth; this similarity may always be perceived, upon minute observation, when there is nothing particularly conspicuous in the formation or position of the teeth. But when the teeth are of a large size, crowded and irregular from the want of expansion in the jaw, defective in the formation of the enamel, or indeed presenting any other peculiarity, the resemblance which the teeth of children bear to those of one or other of the parents is very obvious; and the similarity is equally great in regard to the indentations and fissures upon the surfaces of the grinding teeth, and also the depressions and necks in the interstices between them. I have likewise found, when a predisposition to caries exist in the teeth of a family, that decay generally com-

mences upon the same teeth, and in similar indentations or interstices in the different individuals of the family; and this circumstance alone is a strong corroboration of the principle which I have insisted upon in the former part of this treatise.

“Mr. Bell particularly alludes to this hereditary predisposition of the teeth to caries, and perfectly agrees with me in describing the facts, but differs entirely in assigning their cause. ‘It often happens,’ says Mr. Bell, ‘that this tendency exists in either the whole or greater part of a family of children, where one of the parents had been similarly affected; and this is true to so great an extent, that I have very commonly seen the same tooth, and even the same part of the tooth, affected in several individuals of the family, and at about the same age. In other instances, where there are many children, amongst whom there exists a distinct division into two portions, some resembling the father and others the mother, in features and constitution, I have observed a corresponding difference in the teeth, both as it regards their form and texture, and their tendency to decay.’

“Here Mr. Bell most explicitly confirms what I have stated, as to the hereditary resemblance and hereditary decay of the teeth; and after having observed this similarity of formation, and that decay commonly begins in the same tooth, and even the same part of the tooth, in several individuals of a family, and at about the same age, he misses the only adequate and satisfactory cause, by overlooking the peculiar formation of that part of the tooth where decay first commences; and in order to account for this hereditary predisposition, he again resorts to his vague and improbable theory of an internal and undefined constitutional cause, occurring during the formation of the teeth, and producing in them a disposition to decay.

“In concluding my notice and explanation of the facts to which our attention has just been directed, and from which Mr. Hunter, Mr. Fox, and Mr. Bell have been led to ascribe the predisposition to caries in particular teeth and families, and at certain periods of life, to ‘a disease arising originally in the tooth itself,’ as Mr. Hunter has indefinitely called it, or to some want of healthy action during its formation, as Mr. Fox and Mr. Bell have supposed; I may further remark, with regard to the cause and primary seat of the disease, which all these writers, on the suppositions above named, have concluded to be one originating in the tooth itself, that Mr. Hunter, who was the earliest writer of any authority on the subject, approached much nearer to the discovery of the origin of the decay, although he has left the nature of it undefined, than either of the other authors, who, principally on the facts and conclusions of Mr. Hunter, have severally proposed a theory of the disease as before

stated; in doing which, however, they have not only deviated farther from the true source of the malady, but in many instances have evidently misunderstood the tendency of Mr Hunter’s observations.”

Our author is by no means complimentary to his opponents, and very clearly informs them of their deficiencies. They are however both distinguished writers, and we shall leave them to fight their own battles. Our author next proceeds to describe the progress of caries.

“Having stated what I consider to be the primary cause of caries of the teeth, and pointed out the situations where decay first begins, I shall now endeavour to describe the progress of the disease through its different stages to that period when toothach is produced. When decay commences upon the surface of a grinding tooth the disease is confined to one or more of its deepest indentations, and may be discovered by a brown discoloration of the part, which discoloration is produced by a chemical action of the food lodging in that situation; and as this action proceeds and increases, the bottom of the indentation becomes black and corroded, and soon afterwards (by the application of a pointed instrument) a small opening may be discovered through the enamel. When the putrid substance has been admitted through this orifice to the softer bone within the enamel, decomposition in this situation proceeds with much greater rapidity, whereas the opening through the enamel increases but little, its texture being better able to resist the effects of the chemical action, on account of its greater density; but when decay has proceeded so far as to make an excavation, by the destruction of a considerable portion of the bone under the enamel, the support being removed, the enamel suddenly breaks in during mastication, and a cavity is laid open which, till this period, was not suspected, in consequence of the smallness of the orifice, and the destruction of the tooth, up to this stage of the disease, being unaccompanied with pain. At this period, or soon afterwards, by the continued operation of the same morbid action, the internal membrane that lines the cavity of the tooth becomes exposed, and consequently inflammation occurs, the pain produced by which is toothach.

“The description of the progress of decay above given will equally apply to the disease in whatever situation it occurs, with this difference, that in the interstices of the teeth it is not so easily detected in its first stages, and is seldom found out before an excavation has been made, and a portion of the enamel is broken off. This is more particularly the case with the molares and bicuspidæ whose adjoining surfaces are deeper (particularly those of the molares), and consequently the

seat of the disease is more concealed from view; whereas the lateral surface of the incisors being thinner, the early stage of caries in them is readily discovered."

There is one fact that Mr. Robertson has forgotten to explain, namely, the cause of caries in the interior of the teeth, and this, according to his own shewing, cannot be accounted for in the manner he has proposed. He must, no doubt, have often seen teeth perfectly sound externally though decayed in the centre.

He next proceeds to point out the practical and important application to which his view leads, by shewing the possibility of preventing the commencement of caries, or by arresting its progress before it has done serious mischief. But he first describes the treatment necessary for the preservation of the temporary teeth, and also the means of ensuring the regularity of those teeth which are intended to last through life. This part is so instructive that we shall quote it freely.

"The temporary teeth, although not so liable to caries as the permanent set, are nevertheless the subjects of decay, particularly the molar teeth. The disease generally commences in the interstices of these teeth, and is commonly attended with inflammation of the periosteum and the gums; when this is the case, relief can be obtained only by removing the carious tooth. It is of great importance to preserve those teeth in a healthy state, and to prevent the necessity of their being extracted before the bicuspidæ, which supply their place, are ready to make their appearance; for should it become necessary to remove them early, the permanent molar teeth, which take their stations immediately behind the temporary set, incline towards the front of the mouth, and encroach on the space allotted for the front permanent teeth.

"The only means of prevention that I should recommend, is the daily application of the tooth-brush, with water only, in order to keep the teeth as clean as possible. This simple treatment will be found, to a considerable extent, a preventive of decay in the temporary teeth, and consequently of much pain and suffering; and, moreover, will be of great service by initiating the child into habits of cleanliness, which will afterwards be of the highest importance for the preservation of the permanent teeth. The period at which the temporary teeth become more particularly an object of attention, is at the age of from five to seven years, when they are to be succeeded by a permanent set, more numerous, proportioned to the increased expansion of the jaws, of a larger size, firmer

texture, and better adapted for the purpose of mastication.

"About the age of three years, when the temporary set of teeth are completed, the form of the jaw is that of a semi-circle, and it is filled up to its whole extent with these teeth, twenty in number—ten in each jaw; namely,

Two central incisores, or cutting teeth,

Two lateral incisores, or cutting teeth,

Two cuspidati, or canine teeth.

Four molares, or grinding teeth.

This part of the maxillary arch increases afterwards very little, if at all. In the course of between two and three years from this time, that is to say, a few months previous to the shedding of the temporary teeth, the two extremities of the jaw having elongated posteriorly to allow room for the first molar teeth of the permanent set. These teeth, from the inattention which is so general in the treatment of the temporary teeth, are liable to be affected with caries at an early period; and when it becomes necessary to remove them, in consequence of acute pain produced by decay, the parents are often astonished when they are informed that these teeth belong to the permanent, and not to the temporary set.

"The jaw continues to elongate in the same direction, so as to admit successively of the second molar teeth and the dentes sapientiæ, thus completing the permanent set; and at this period, the jaw, which at the completion of the temporary set, presented the form of a semi-circle, approaches to that part of an ellipsis, or, in other words, resembles a horse-shoe in shape. According to this arrangement of nature, it will be seen that the room occupied by the twenty temporary teeth is filled with the same number of permanent teeth; but as the teeth of the two successive sets are not respectively equal to one another in size, it will here be necessary to explain how they come to be arranged in the same space. This is of the more importance, as the irregular position of the teeth is one of the principal predisposing causes of caries.

"The incisores and cuspidati of the permanent set are considerably larger than the corresponding teeth of the temporary set; whereas the molar teeth of the temporary set are much larger than the bicuspidæ of the permanent set, which succeed them. And here it is obvious, that the additional room required for the permanent incisores and cuspidati is compensated by the smaller space occupied by the bicuspidæ.

"The formation of the maxillary arch in different individuals is exceedingly various. When we find the jaw sufficiently expanded, and the temporary teeth a little separated from each other, the arrangement of the permanent set may be safely left to nature; but when the jaw is contracted, and the temporary teeth arranged closely together, it becomes

necessary, in order to ensure the regularity of the permanent teeth, that nature should be assisted; and with judicious management, there are but few cases which are not under the control of the operator, by the removal, from time to time, of the temporary teeth, to make room for those of the permanent set which succeed them.

"The shedding of the teeth commences with the central incisors of the lower jaw; sometimes the fangs of these teeth are absorbed, and their crowns fall out spontaneously, that is, when the permanent teeth come up immediately under them. But even when this is the case, the space previously occupied by these teeth may be too narrow to admit of the permanent teeth; and if so, they are forced out of the circle by the contiguous temporary teeth, and stand either obliquely or the one before the other. In order to remedy this defect, it becomes necessary to remove the lateral temporary incisors; and for the same reason, when the lateral permanent incisors make their appearance, the temporary cuspidati must be removed to make room for the lateral permanent incisors.

"When the permanent incisors of the lower jaw appear behind those of the temporary ones, absorption does not take place in the fangs of the temporary teeth, and consequently they remain firm in their sockets; nevertheless they ought to be removed, in order to admit of the permanent teeth coming forwards into place.

"Similar treatment to that above described will be necessary for the regulation of the teeth in the upper jaw. When the temporary incisors and cuspidati have been removed, a considerable period may be allowed to elapse before any further assistance is requisite. In twelve or eighteen months from this time, the fangs of the temporary molar teeth become absorbed, the bicuspidates generally coming up immediately under them, and their crowns drop out of their own accord, or become so loose as to be easily removed; but should the bicuspidates take an irregular direction, either inside or outside of the circle, the temporary tooth must be removed to allow the permanent one to take its place.

"The cuspidati seldom appear before all the temporary teeth have been shed, and the bicuspidates and incisors have been arranged in their respective situations; and these teeth, the bicuspidates and incisors, sixteen in number, frequently fill up the whole of the space previously occupied by the twenty temporary teeth, so as to prevent the cuspidati, particularly those of the upper jaw, from falling into the circle. In this case, the cuspidati occasion great deformity by projecting beyond the range of the other teeth. Unskilful practitioners frequently remove these teeth, in order to remedy the deformity, thereby destroying the symmetry of the

mouth, and sacrificing a class of teeth which, from their strength and durability, are of the greatest importance in after life; whereas the removal of the anterior bicuspidates, which are teeth of much less consequence, because more liable to decay, and the abstraction of which does not interfere with the symmetry of the month, would effect every purpose by allowing the cuspidati to fall into their proper places in the arch of the jaw. The remaining teeth which have yet to appear, are the second molares and the dentes sapientiae, which take their places in due course, and complete the permanent set.

"Before dismissing this part of the subject, I shall point out some of the bad effects which result from inattention to the teeth during that period which is termed the shedding of the teeth. We have before stated that when the teeth are irregular in their arrangement they are more subject to caries, inasmuch as there are situations produced by this irregularity calculated to retain particles of food, which in a well-arranged set of teeth would not be the case; and moreover, that it is scarcely possible to prevent an accumulation of a substance called tartar from taking place on those teeth which stand out of the range, as they escape the friction of the brush during the process of cleaning. The irregularity of the teeth in many instances also occasions very considerable deformity in the appearance of the face; this is more particularly the case when the upper front teeth, instead of closing over the lower ones, shut within them, and consequently give an unnatural projection to the lower part of the face. When one or more of the teeth take this position, it becomes necessary to have recourse to artificial aid, otherwise the defect will be permanent. In order to rectify this deformity, a plate is adapted to the lower range of teeth, and so constructed as to produce pressure upon the irregular ones; by which contrivance the rest of the teeth are prevented from coming in contact with each other, and the whole pressure of the mouth in shutting is thrown upon the irregular teeth, which act against the inclined surface of the plate, and by degrees are moved forwards into their proper situations."

Our author now arrives to consider the means of preventing and curing diseases of the permanent teeth, which every one, medical or non-medical, ought to peruse with attention. He endeavours to prove, but he does not do so in our opinion, that caries is most frequent in early life, for example, from the age of fifteen to twenty. He states—

"In the early periods of life too, the progress of decay is more rapid in effecting the destruction of the teeth, because the interna

cavity of the tooth being larger, and the wall of bone between the cavity and enamel being consequently thinner, the disease has a shorter distance to penetrate before it accomplishes the exposure of the internal membrane; whereas, in the middle and later stages of life, the bony partition becomes considerably thickened, so as to increase the distance between the surface of the tooth and the cavity. It also too often happens, and is another cause of the frequency of caries during the period of youth, that, at this time, when the greatest liability to the disease exists, the precautionary measures for preserving the teeth are the most neglected; and it is only after acute suffering and irremediable mischief have been produced, by the loss of several teeth, that means are adopted for preserving those which remain.

"The first, and one of the most important precautionary measures to be adopted, is that of cleanliness; and I have been the more particular, on a former occasion, in insisting upon the early use of the tooth-brush, not only as the means best calculated for the prevention of decay in the temporary teeth; but in order to establish and confirm those habits of attention so necessary for the preservation of the permanent teeth.

"In order to preserve the teeth from caries it is absolutely necessary that they should be brushed once in twenty-four hours, and so effectually as to remove any portion of food which may have adhered to them. This will prevent the remains of food from suffering decomposition in the situations already described, the putrid matter arising from which has been pointed out as the active agent of destruction; it is better, however, to clean them morning and night; but the strict rules of cleanliness require the use of the brush at the termination of every meal.

"The ablution of the teeth, in many instances is performed in that superficial manner which does little or nothing for the prevention of decay. The operation of the brush is generally confined to the front teeth; and whether confined to these or extended over a larger range, it is almost always applied across their anterior surfaces only; and the irregularities upon the masticating surfaces of the double teeth, and the interstices in which the food is the most liable to lodge, and consequently the most subject to decay, are altogether neglected.

"The most effectual method for removing the particles of food from the interstices of the teeth is to brush them upwards and downwards, and the brush should be firmly applied across the masticating surfaces of the double teeth; and if it were possible by these means to keep the teeth perfectly clean, and to dislodge all the food which is retained in their indentations and interstices before decomposition could take place, it is not improbable that caries would be as seldom

met with in the teeth as in other bones, in which it sometimes takes place indeed, but is a circumstance of rare occurrence. But it must be allowed that, in a vast number of cases, from the deeply indented and irregular structure of the teeth, it is not practicable, by the most rigid attention to the rules of cleanliness, to prevent the decomposition of food in some of the situations already noticed; the consequence of which is that decay must and does ensue; and here it is obvious that another mode of treatment becomes necessary in order to arrest the further progress of the disease.

"I scarcely need remark that the only treatment which can be adopted under these circumstances, for the preservation of the teeth, and the only one which has ever been found effectual, consists in filing away the carious part, or in eradicating the spongy and decayed portion, and subsequently filing the cavity which the disease has produced. But such, unfortunately, is the insidious character of the disease, and so unacquainted are the generality of people with its nature and progress, that application is rarely made for assistance until it is too late to be effectual. This false security, which is so common among mankind, arises from a prevailing prejudice that, as in the other organs of the body, so in the teeth, disease cannot commence without pain. This impression is so generally true, with respect to diseases of most of the internal organs, whose functions, being immediately necessary to life and health, cannot be deranged without uneasiness and suffering, and also to most of the external parts, which are endowed with such extreme sensibility that the slightest and most superficial injury causes acute pain, that it has become a received principle with respect to the diseases of all parts of the system.

"Persons are either ignorant, or do not consider, that the enamel of a tooth is an inorganic substance, and perfectly insensible, and that the bony structure beneath is so void of feeling, that disease may effect the destruction of these parts without pain or suffering. They are further so universally led to believe that decay originates in the internal structure of the tooth, and that the exciting causes operate by inducing some internal morbid process, terminating in inflammation of the membrane or of the bony substance of the organ, that they have never suspected the true cause to be a chemical agent acting upon the external crust and material substance of the tooth itself.

"The consequence of these misconceptions is that the practitioner is hardly ever consulted before pain has been experienced; and, in not a few instances, it is a subject of surprise to the patient when told that the disease is irremediable, and that the only resource is the extraction of the tooth.

"The facts just stated, with regard to the

almost imperceptible approach of caries of the teeth, will, I trust, sufficiently impress on the mind of the reader the necessity of a careful and continual watchfulness over these organs so important to health and comfort, for the purpose of detecting the disease in its first stages, before it has proceeded so far as to produce pain or even tenderness.

"This attention to the teeth should commence at the early age of six or seven years, when the first molar teeth of the permanent set have pierced the gums. As these teeth are very subject to decay soon after they have made their appearance, it therefore becomes the duty of the parents and guardians of the young, to have the teeth regularly inspected, and this examination should take place at least once in every twelve months; and to insure their safety should be continued throughout the future periods of life. If this system were more generally adopted, the necessity of extracting teeth, which so constantly arises, would be of less frequent occurrence, and consequently much pain and inconvenience would be prevented.

"An experienced practitioner will have no difficulty in discovering the first stages of caries; nay, from the first appearance of the teeth through the gums, he will be able to foresee, from their construction, which and what parts of them are predisposed to the disease. The only situations where caries may commence and proceed without detection till it becomes incurable, are the interstices of the double teeth; and even in those situations, in a vast majority of cases, the disease may be detected before much mischief has been produced.

"The object and advantages proposed by the system of constant watchfulness and regular inspection of the teeth now suggested, are to arrest the progress of decay before it has penetrated to the internal cavity of the tooth and exposed its vascular membrane to the influence of foreign bodies; this is accomplished by filing away the carious part, or by eradicating the spongy and decayed portion, and subsequently filling the cavity which the disease has occasioned. For the successful practice, however, of either of these processes, it is evident that we ought to have a clear idea of the object proposed by them.

"The cause of caries being, as we have minutely pointed out, the corrosive action of decayed particles of food, it must be obvious that the method that we propose for preventing the further progress of the disease, must consist in remedying the peculiarity of structure which led to it. If, for example, decay takes place in one of the deepest indentations of the masticating surface of a grinding tooth, in order to arrest its progress, the decayed part is removed and the cavity stopped up; consequently a future lodgement of food is prevented."

Here we shall pause for the present, and conclude our remarks in a future number.

The New London Dispensatory, containing a Translation of the Pharmacopœia Londinensis, with the Medical, Natural, and Pharmaceutical History of the Articles in the Materia Medica; also, a Translation of Magendie's Formulary for the Preparation and Employment of several New Remedies.
By Thomas Cox, M.D., and Charles Wilson Gregory, M.D. Svo. pp. 577.
London: E. Cox. 1835.

THIS is an accurate English version of the London Pharmacopœia, to which is appended a translation of M. Magendie's Formulary for the preparation and employment of several new remedies, from the eighth edition, published in Paris, 1835. The authors have acted wisely in combining both works, as the latter contains all modern discoveries, while the former is no credit to any country. It does not contain a single new medicine, but abounds with a pile of trash which nobody employs. In saying this, we are aware that the *magnates* of the college have been talking about publishing a new edition of their Pharmacopœia; but as a few of them are in very extensive practice, and most of them in the habit of prescribing placebos, they are totally incompetent to execute the work which the legislature has most unfortunately empowered them to revise. The consequence is, that after seven years' squabbling about the new edition, and after the premeditated insult of excluding the members illegally designated licentiates, their worship have been compelled to confide the arrangement of their new edition to a gentleman, of great talent as a chemist, but who is not one of their body, either fellow or member, and who justly reprobated their last impression, as well he might, in the roundest terms. They have, however, no qualms about the

Sic vos non nobis,
and the forthcoming edition will be chemically correct; but as to its therapeutical excellence, it remains to be estimated.

We cannot conceive why there could not be an annual or triennial edition of the British Pharmacopœias, and all new medicines, after satisfactory trials, included.

Every one who compounds prescriptions, and every one engaged in medical practice, who wishes to follow the London Pharmacopœia, and more especially the inestimable work of M. Magendie, is now afforded the

opportunity on very moderate terms. The translators have executed their respective tasks with great fidelity and ability. The defects of the first are well supplied by the second work; and the combination of both is judicious and valuable. What a contrast between the English and French productions! but *jam satis*. Nevertheless, our brethren in the aggregate, for us, at the bedside; for after all, there are few Magdemies.

The London Medical

AND

Surgical Journal.

Saturday, October 17th, 1835.

—

NEW ARRANGEMENTS FOR THE FUTURE CONDUCT OF THIS JOURNAL.

THE very rapid increase in the sale of this journal within the last few months, has induced us to enter into arrangements attended with so great an expense that they would have been imprudent under circumstances less auspicious.

It has always been our ambition to raise the London Medical and Surgical Journal to the first rank among medical hebdomadals; and this object we have endeavoured to attain, not by the violent and extravagant declamation in which some of our contemporaries have indulged, nor by the low malevolence and dastardly attacks on private character, which have brought others into general and deserved contempt, but by a fearless exposition of principles which we hold in common with all honourable and enlightened men in the profession—by impartial and elaborate criticism—and by unwearied assiduity in following the progress of medical science, and recording its improvements in our own and other countries. After encountering a degree of opposition which showed how much was feared from our success, and surmounting obstacles which might have discouraged the most sanguine, we are now fast approaching to the consummation of our wishes. This journal has already acquired a stronger hold on public opinion than any of its weekly

contemporaries; its circulation is very nearly equal to that of the longest established among them, and, if it go on increasing in its present ratio, it will very soon far exceed that of any medical journal ever published. Under these circumstances, expense becomes a subordinate consideration; accordingly we have resolved to consult nothing but the improvement of the journal, and have just concluded arrangements which will bring some of the highest professional talent in the kingdom to bear on its progress. We have moreover engaged eminent artists, whose labours will afford the work every advantage of graphic illustration; we may refer to what has already been done in this way as an earnest of what may be expected. Our engravings have actually excited emulation in the Green Lizard, which has followed us "*non passibus æquis*," by a truly ludicrous exhibition of certain stampings from wooden blocks—we rather think the heads of some of the chief contributors must have been put in requisition, to say nothing of that "*triste lignum*," the editorial scone itself.

Paulo majora canamus. Aware of the importance of lectures to a weekly journal, we have spared no exertions to supply our readers with the best that could be obtained on each subject. We have much pleasure in announcing that Dr. Fletcher's unequalled course on physiology will be resumed in January next. A course of lectures on obstetrics will be speedily commenced by Dr. Ryan, which will be fuller and more comprehensive than any hitherto published on that subject; it will also be illustrated by a series of fine engravings on copper. We expect soon to bring our negotiations with some of the Parisian lecturers to a satisfactory conclusion, nor are we without a hope that we may ere long be able to present our readers with a German course—to this, however, we cannot at present pledge ourselves.

With respect to those departments which are more under our own control, it is hoped that the accession of talent which this journal has received, will immediately become perceptible.

The reviews of English works on physic will be written by gentlemen whose extensive practice, and long connexion with the medical literature of this country, eminently qualify them for the task. Publications on surgery will be criticised by distinguished members of that branch of the profession. Foreign works will be reviewed by gentlemen familiar with the peculiarities of continental practice, and intimately conversant with the French, German, and Italian languages. Finally, the department of foreign medicine, and that of hospital reports, will be no less efficiently filled by gentlemen in whose intelligence and accuracy we can place entire confidence.

With regard to original communications, our pages will always be accessible to such as possess sufficient interest, and we may add, that in future, illustrative drawings transmitted along with any paper, will be accurately engraved and inserted in the journal.

Such are the grounds on which we are conscious of deserving, and certain of obtaining, the continued support of the profession. Our course has been an adventurous one, but it has been crowned with success equal to our own most sanguine expectations.

"Serpit humi tutus nimium timidusque procellæ!"

—o—

PROFESSOR TIEDEMANN IN LONDON.

—

PROFESSOR TIEDEMANN, of Heidelberg, is at present in London. This distinguished foreigner will no doubt be gratified at viewing the extensive materials collected in the Museum of the College of Surgeons, for the illustration of those branches of science to which he has himself been an eminent contributor. And he will probably expect to find the guardians of this invaluable mu-

seum not only deeply informed on the subjects to which its contents have reference, but zealous to diffuse such information through the medical community. He will be disappointed; these dog-in-a-manger rogues, who have stolen John Hunter's museum, take good care to keep the profession excluded from all effectual access to it, although they are themselves so careless about it that the greater part of them have not the most distant idea of what it contains.

Ah! these curs! And it is to them and to their analogues in Pall Mall, that the medical philosophers of other countries are introduced as to the "heads of the profession" in this. Is it wonderful that those philosophers go away with the firm conviction that we are the most leather-headed profession on the face of the earth? Alas! they know not that they are brought in contact with the nethermost part of the profession, and take our "eel of science by the tail." The idea entertained of us by foreign physicians is, that we are a set of peculiarly gifted noodles, who by some incomprehensible instinct are enabled to cure our patients remarkably well, but without knowing why.

In a few years the aspect of things will be changed. When one faculty is established, it will shew its real heads, instead of the queer tuberosities—the amorphous bumps—which are now presented to the wonder and ridicule of our brethren of other lands!

—o—

Ointment to Allay the Irritation of Hemorrhoidal Tumours.

So much suffering is experienced from the incessant irritation of hemorrhoidal tumours, that every means capable of affording relief under such circumstances, must prove acceptable to the profession. I have used an ointment similar to the following, with the most happy effects, and in a great number of cases:—

Rx. Pulv. carb. plumbi, ʒ ss;
Sulph. morph., gr. xv;
Unguent. stramon., ʒ i.

Ol. olivar. q. s. M. ft. unguent. part. applicand.

Powdered opium, to the amount of a drachm, may be substituted for the morphia, and if the dry white lead is not at hand, that which is ground in oil, for the use of painters, may be advantageously substituted. Sometimes a drachm of powdered galls may be added.—*North American Archives of Medical and Surgical Science. Edited by Dr. Geddings. October, 1834.*

Foreign Medicine.

Encephalocele mistaken for a Wen.

AN infant of six weeks old had a tumour at the posterior part of the head, very nearly in the middle of the occiput, which was rather voluminous, and appeared slightly strangulated at its base. Pressure upon it caused no bad effects; there was no pulsation perceptible: the surgeons that examined it differed in opinion: some pronouncing it to be a wen, while others said it was a tumour of the brain. Palliative treatment was employed, but the tumour continued to enlarge; a consultation was held, the tumour was considered to be a wen, and was opened. A considerable quantity of serosity flowed from it, and then it was perceived to be formed by a portion of the cerebral substance. It was easy to foretell the result. The infant seemed to feel no bad effects for the first few days (as the wound was probably quickly closed), but sank on the eighth day after the operation (from a true encephalitis). On a *post mortem* examination, the ossification of the bones of the two superior portions of the occiput were found to have been suspended; and the tumour was formed by the protrusion of the left posterior lobe of the brain. This observation serves to confirm the opinion of those, who maintain that any doubtful tumours of the cranium should never be meddled with. There are two or three cases of the same sort related by M. Geoffroy-Saint-Hilaire, in his *Treatise on Monstrosities*.—*Journ. Hebd.*

Pretended Specimen of a Fossil Man.

In a letter written to M. Arago, and communicated by him to the Academy, M. Bernard announced that in the grotto of Gigny, between Bourg and Lous-le-Saulnier, were found some bones, which were designated *the fossil man*, and that these pieces were sent to Paris for the purpose of being examined. The skull of this man was seen by MM. Cornier, Flourens, and Dumeril, but these naturalists could find nothing that would warrant them in considering it a fossil. On the contrary, they found only charcoal and dust, and there were none of the bones of antediluvian animals found in the vicinity in which the former were discovered: they were

in the same state as the other human bones, which were supposed to be in a fossil state. They regarded them as an incrustation of a human head, which had been buried in the grotto of Gigny as if it had been in a catacomb.—*Op. Cit.*

What is the relation between Hemoptysis and Pulmonary Tubercles? By M. Frédéric Cuvier.

We shall confine ourselves to an extract of the conclusions, because they are perfectly well deduced from the rational and practical considerations which constitute the basis of this interesting work. 1st.—There is no necessary relation between hemoptysis and pulmonary tubercles: there is hemoptysis without tubercles; and there are tubercles without hemoptysis. 2nd.—Hemoptysis alone is not sufficient to constitute a diagnostic of tubercles; it must be supported by other corresponding signs, or by hereditary disposition, or by constitution, or other circumstances in life. 3rd.—If it be difficult to prove by observation, that hemoptysis produces pulmonary tubercles, there are, nevertheless, some facts which prevent the adoption on this point of the too exclusive ideas of Bayle and Laennec. 4th.—Hemoptysis is an extremely frequent symptom in adults, of the presence of pulmonary tubercles; it is very rare in children, and is never observed in animals. 5th.—Hemoptysis appears much more frequently before the period of softening of the tubercles than afterwards. 6th.—Hemoptysis is, in general, a more formidable symptom of the danger that is to follow, than of that which immediately accompanies it.—*Op. Cit.*

Case of acute Anasarca, successfully treated by punctures of the inferior Extremities.

A man, aged thirty-one years, of sanguineous temperament, of a good constitution, who never had suffered from serious disease previously, was attacked on March 10, 1835, with intense rigor, but of short duration, in consequence of laborious exertion, during which, all his body was covered with perspiration, and exposed without any precaution, to the effects of the atmosphere. The following day he complained of violent headache, all his limbs felt as if bruised with

blows; he was feverish, had intense thirst, and was obliged to leave his work and go to bed; he was then brought to the hospital.

A copious bleeding would undoubtedly have arrested the disease in the commencement; but the pupil who had the care of the patient, had the misfortune to miss the vein. The following days the inflammatory symptoms decreased, but the patient was quite surprised to perceive the inferior extremities swell first, and then the abdomen, scrotum, skin of the penis, face, arms, and all the external surface of the body. Being dissatisfied with the treatment which he received in the hospital, he returned home, more swelled, and worse than ever.

[This was on the 29th of March, when I saw him for the first time; he was in the following state: prostration, great dejection of mind, parching thirst, strong, frequent, and full pulse, head-ache, insomnia, the face pale and swelled; the hands, arms, thorax, and abdomen, very œdematous; the skin on all parts of the body retained for a long time the impression of the finger; the scrotum, which was enormously distended, resembled a bladder filled with serosity; the penis was as if lost in the enormous swelling of its sheath, the inferior extremities were twice as large as in the normal state.

My first care was to rouse the patient's spirits; I then prescribed a bleeding with refrigerating and diuretic drinks, which relieved the headach, calmed the pulse, caused sleep, and copious and clear urine, which had been scanty and thick.

The powder and tincture of digitalis, employed internally and externally, though continued for some time, and in increased doses, caused no amendment, and general œdema still continued.

Drastic purgatives were not more successful, they diminished however, the swelling of the abdomen, but this amelioration was but of short continuance. Blisters applied to the internal surface of the thighs were much more advantageous, and frictions with tincture of veratrine were employed three times a day, over the whole surface of the body.

The blisters discharged a prodigious quantity of serosity; the swelling of the face, arms, abdomen, and scrotum abated; but, notwithstanding all my efforts, I could not obtain a radical cure by the use of these edies.

Wearied by the failure of these different remedies, the patient at length consented to my request, and allowed me to make eight punctures with a lancet in the inferior extremities, at the union of the lower third with the upper two thirds of the leg: a great quantity of serosity flowed from the punctures, the patient from being swelled and œdematous, in three or four days became thin, and free from exudation. Frictions with the tincture of veratrine, were continued all the time, and no bad effects resulted, except severe pain, which continued for several hours in the incisions made in the internal part of the left leg. This pain extended to the heart, and caused some faintness. It yielded, however, to the use of a small cataplasm of linseed meal, wetted with thirty drops of laudanum. The patient was completely cured of his anasarca, when from his haste in returning to his work too soon, he was attacked with pneumonia, for which he was bled three times, and thirty leeches and a blister applied. On the 15th of May he was recovered from this disease, and since then his health is perfectly re-established. M. Berard.—*Journ. Hebd.*

ITALIAN MEDICAL INSTITUTIONS AND HOSPITALS.

THE following are a few extracts from Mr. Lee's work, of which a notice appeared in our last number.

The medical institutions of Italy are regulated much in the same manner as in France, being under the superintendence of their respective governments, and deriving their revenues from property with which they have been endowed, and from the bequests and donations of rich individuals. In most of the hospitals a director is invested with supreme power, and the election of medical officers is mostly decided by concours. Those officially connected with the medical establishments receive salaries; medical visits are made daily at an early hour. The patients are usually admitted on application, and are attended by a religious sisterhood, with subordinate male and female attendants; the bodies of those who die are examined, and supply the dissecting rooms, although the Italians are not in general very zealous in the cultivation of either natural or morbid anatomy.

The profession is divided as in France, into physicians, surgeons, and obstetric practitioners. The division between medicine and surgery is in some parts very arbitrary, the duties of the surgeon being confined to the application of local remedies and operations, while the physician is called

in to prescribe for the constitutional disorder accompanying surgical disease.

The principles by which the practice is guided, necessarily vary in the different states: at Florence and Rome they are based upon the Broussaisian doctrine much more generally than at Naples or Milan; but with the exception of the last city, the treatment of disease is infinitely inferior to the French. The number of followers of the Rasorian doctrine of contra-stimulus has very much diminished of late years, and the practice of giving large doses of antimony to supersede blood-letting in acute disease is comparatively rarely employed. The abstraction of blood from the system in small quantity at a time, is a mode pretty generally adopted, as are also blistering, baths, and lavements; sedatives are likewise frequently prescribed, but purgatives, tonics, and stimulants, are more sparingly used.

The Italians do not speedily adopt innovations, and auscultation, percussion, and lithotrity, meet with no advocates among them. In surgical cases little or no medicine is given; patients who die after accidents and operation, usually succumb to constitutional irritation or internal inflammations; hospital gangrene is also a frequent cause of death in some parts. The greater temperance of the Italians, however, and the purer air of their cities, render them less liable to severe inflammatory attacks and derangement of the general health, which so frequently supervene in surgical cases in England.

PARMA.

The *Spedale della Misericordia* has a plain exterior, but the principal wards are handsome, lofty, extremely clean, and airy. The clinical wards, and those for the military, are small, and not so well ventilated as the others. The hospital contains four hundred beds, but in May, 1834, not more than half these were occupied. There are four physicians and two surgeons. Rasori and Tommassini, the originators of the contra-stimulant theory, are professors of clinical medicine.

This doctrine supposes that life is the result of two forces, viz. stimulus, or excess of action; and contra-stimulus, or debility. These opposing forces, in a healthy state of the system, counterbalance and maintain each other in a state of equilibrium; but when one or the other preponderates, the healthy condition is destroyed, and disorder ensues. Hence the supporters of this system admit only of two orders of diseases—those from excessive excitement, and those from debility. This last condition is not considered merely as a negative state, or absence of stimulus, as in the Brunonian doctrine; but is regarded as the product of an active power, independently of the opposing force. Remedies are also divided into stimulant and contra-stimulant: among

the former may be enumerated tonics, opium, spirituous preparations: the latter include all agents which tend to lower vascular action; of these, antimony was most frequently had recourse to, and was exhibited in very large doses, being in many cases made to supersede sanguineous depletion. This practice counted, a few years ago, numerous followers, but is now made accessory to the other measures, and bleeding is carried to a greater extent in Parma than in most parts of Italy.

BOLOGNA.

The *Spedale St. Orsola* receives patients with chronic, syphilitic, and cutaneous diseases. There is also a department for the insane, about one hundred in number, who are lodged in four long corridors, separate from the rest of the hospital, and warmed by stoves in winter. The division for either sex contains a ward of about fifteen beds, twenty-eight cells, and a small ward for convalescents. The patients appear to be treated with gentleness. Contra-stimulant remedies are mostly employed, and the more violent patients are treated by low diet, confinement by the strait waistcoat, the cold, and surprise bath.

There is also a small, well arranged, clinical hospital, of about fifty beds, adjoining the university, where the most interesting cases are sent for the instruction of pupils. At each bed a paper is placed, stating the circumstances connected with the case. Two or three rooms are set apart for those persons who pay something towards their own maintenance.

The university is a handsome edifice, inclosing a spacious court-yard, and containing a fine library; an amphitheatre for the delivery of lectures; museums of antiquities, of comparative anatomy, of natural history, and of human and pathological anatomy. In this last are several wax models of healthy and diseased structure. Those illustrating the pellagra, and morbus ceruleus, are exceedingly well executed. There is also an interesting cabinet of casts, illustrating the progress of utero-gestation, anomalous presentations, monstrosities, &c.

This university, formerly the most resorted to of any in Italy, is now but thinly attended, the number of pupils being reduced to between four and five hundred, and most of the lectures are delivered at the houses of the professors. Political circumstances are said to be the causes of this change. Among the celebrated men who studied at Bologna, are Valsalva, Malpighi, and Galvani, to whom a monument is erected in one of the corridors.

Medical students are obliged to attend the classes during four years, in the following order:—first year, natural history, botany, chemistry, anatomy; second year, anatomy, physiology, comparative anatomy, institutes of surgery; third year, pathology, clinical medicine, materia medica, chemistry; fourth

year, pathology, clinical medicine, medical jurisprudence, and midwifery. During the last year of study, a certain number of patients are placed under the care of each pupil, who, previous to his examination, has to give an account of the cases, and of the treatment he has adopted. Surgical students attend during the first and second years the same courses of lectures as the medical pupils; third year, institutes of surgery, clinical surgery, anatomy, and dissections; fourth year, medical jurisprudence, midwifery, dissections, clinical surgery, and the performance of operations on patients, under the guidance of the professor. At the termination of the first year, students take the degree of bachelor; at the end of the second year, of licentiate; and at the end of the fourth year, of doctor of medicine or surgery.

The mode of examination of candidates is as follows: five professors of the different branches of education submit each to the candidate twenty different subjects, taken from his own course of instruction: the pupil draws one of these by lot, and is examined on that subject. Thus the candidate is examined on five subjects connected with medicine. When the examination is finished, each of the professors gives his vote separately, as to the fitness of the candidates; those who are considered not sufficiently qualified, have to study during another year.

FLORENCE.

The most prevalent diseases at Florence are acute and subacute inflammation of the lungs, pleurisy, bronchial affections, dysentery, gastric irritation, rheumatism, and diseases of the eyes.
